## Abstract

Avis, D., P. Erdős and J. Pach, Distinct distances determined by subsets of a point in space, *Computational Geometry: Theory and Applications 1 (1991) 1–11*.

We answer the following question posed by Paul Erdős and George Purdy: determine the largest number  $f_d(k) = f$  with the property that almost all  $k$ -element subsets of any  $n$ -element set in  $\mathbb{R}^d$  determine at least  $f$  distinct distances, for all sufficiently large  $n$ . For  $d = 2$  we investigate the asymptotic behaviour of the maximum number of  $k$ -element subsets of a set of  $n$  points, each subset determining at most  $i$  distinct distances, for some prespecified number  $i$ . We also show that if  $k = o(n^{1/7})$ , almost all  $k$ -element subsets of a planar point set determine distinct distances.

## 1. Introduction

Let  $k, n$  be natural numbers,  $k$  fixed and  $n$  very large. Given a set of  $k$  points  $S_k = \{p_1, \dots, p_k\}$  in Euclidean  $d$ -space, let  $|p_i - p_j|$  denote the distance between  $p_i$  and  $p_j$ , and let  $D(S_k)$  denote the number of distinct values of  $|p_i - p_j|$ ,  $1 \leq i < j \leq k$ . The following problem was raised by Erdős and Purdy [5]. Determine the largest number  $f_d(k) = f$  with the property that almost all

$k$ -element subsets of any  $n$ -element set  $S \subseteq \mathbb{R}^d$  determine at least  $f$  distinct distances, that is

$$\min_{\substack{S \subseteq \mathbb{R}^d, \\ |S|=n}} \frac{|\{S_k \subseteq S: |S_k|=k \text{ and } D(S_k) \geq f\}|}{\binom{n}{k}} \rightarrow 1$$

as  $n$  tends to infinity. In Sections 2 and 3 we obtain matching upper and lower bounds for  $f_d(k)$  when  $d \geq 3$ .

It is not difficult to see that  $f_1(k) = f_2(k) = \binom{k}{2}$  for every integer  $k$ . In fact, these equations follow from the general theory developed in Section 3. As Erdős and Purdy suggested almost 20 years ago, it might be interesting to investigate the following more delicate question. Given  $0 < i \leq \binom{k}{2}$ , determine or estimate the asymptotic behaviour of the function  $h_d^{i,k}(n)$ , the maximum number of  $k$ -element subsets  $S_k$  of an  $n$  element set  $S \subseteq \mathbb{R}^d$  with the property that  $D(S_k) \leq i$ , that is,  $S_k$  determines at most  $i$  distinct distances. Obviously,

$$h_d^{i,k}(n) = o(n^k) \quad \text{for all } i < f_d(k),$$

$$h_d^{i,k}(n) = \Omega(n^k) \quad \text{for all } i \geq f_d(k).$$

(For nonnegative functions  $f$  and  $g$  defined on the natural numbers, we write  $f(n) = \Omega(g(n))$  if  $f(n) \geq c g(n)$  for some positive constant  $c$  and all sufficiently large  $n$ .) However, even in the plane it seems to be a hopelessly difficult task to determine the exact order of magnitude of these functions. For simplicity, we shall write  $h^{i,k}(n)$  instead of  $h_2^{i,k}(n)$ . In particular, we are very far from knowing the answer to the following old problem of Erdős: What is the smallest value  $k(i)$  for which

$$h^{i,k(i)}(n) = 0$$

holds for all  $n$ ? It is conjectured that  $k(i) = O(i \log^{1/2} i)$ , and the best currently known bound  $k(i) < i^{5/4} \log^c i$  is due to Chung, Szemerédi and Trotter [1]. In Section 4 we obtain some results on  $h^{\binom{k}{2}-i,k}$  for  $1 \leq i \leq k - 2$ .

## 2. Upper bound for $f_d(k)$

For  $d \geq 3$  upper bounds on  $f_d(k)$  come from the so-called Lenz examples (see [3]). For even  $d$ , set  $t = d/2$ , and fix  $k$ . For any give large  $n$ , distribute  $n$  points as evenly as possible amongst  $t$  mutually orthogonal unit circles with common centre, so that each circle contains either  $\lfloor n/t \rfloor$  or  $\lceil n/t \rceil$  points. Every pair of points chosen from distinct circles determines the same distance. Now consider a  $k$ -tuple  $S_k$  where the points are again chosen as evenly as possible from the  $t$

circles. Then it can easily be verified that  $D(S_k) \leq g_d(k)$  where

$$g_d(k) = \begin{cases} 0 & k = 1, d \text{ even}, t = d/2; \\ 1 & k = 2, d \text{ even}, t = d/2; \\ g_d(k-1) + \lfloor (k-1)/t \rfloor & k \geq 3, d \text{ even}, t = d/2. \end{cases} \quad (1)$$

It is easy to see that we can choose an  $\varepsilon > 0$  for which at least  $\varepsilon n^k$   $k$ -subsets of the  $n$  points have the above property. This implies that  $f_d(k) \leq g_d(k)$ .

For odd  $d$ , set  $t = \lceil d/2 \rceil$ , and fix  $k$ . For any given large  $n$ , distribute  $n$  points as evenly as possible amongst  $t$  sets consisting of  $t-1$  mutually orthogonal unit circles with common centre and the line passing through the common centre orthogonal to all of the circles. Now again every pair of points chosen from distinct circles determines the same distance. However the points on the line each determine a distinct distance to the circles. Now consider a  $k$ -tuple  $S_k$  where the points are again chosen as evenly as possible from the  $t$  sets. In case of an uneven division, we choose  $\lfloor k/t \rfloor$  points from the line. Then it can easily be verified that  $D(S_k) \leq g_d(k)$  where

$$g_d(k) = \begin{cases} 0 & k = 1, d \text{ odd}, t = \lceil d/2 \rceil; \\ 1 & k = 2, d \text{ odd}, t = \lceil d/2 \rceil; \\ g_d(k-1) + \lfloor k/t \rfloor & k \geq 3, d \text{ odd}, t = \lceil d/2 \rceil. \end{cases} \quad (2)$$

Again, this implies that  $f_d(k) \leq g_d(k)$ . Our main result is to show that these bounds are in fact tight, that is  $f_d(k) = g_d(k)$ .

It is convenient to get a closed form expression for  $g_d(k)$ , which we now do in terms of the Turán number  $T(k, t+1)$ , which is the maximum number of edges in a graph on  $k$  vertices which does not contain a  $K_{t+1}$ . Turán showed that

$$T(k, t+1) = \frac{(t-1)(k^2 - r^2)}{2t} + \binom{r}{2}$$

where  $r$  is the remainder of  $k$  upon division by  $t$ . This bound is obtained for the so-called Turán graph, that is, a complete  $t$ -partite graph formed by distributing the  $k$  points into  $t$  parts as evenly as possible. Consider the Lenz example with  $d$  even and  $t = d/2$ . The number of distinct distances in an evenly distributed  $k$ -tuple is just the number of edges in the complement of the Turán graph plus one for the distance between the circles, so that

$$g_d(k) = \binom{k}{2} - T(k, t+1) + 1, \quad d \text{ even}. \quad (1')$$

When  $d$  is odd, let  $t = \lceil d/2 \rceil$ . Then the number of distinct distances in an evenly distributed  $k$ -tuple in our construction is the number of edges in the complement of the Turán graph, plus one for each point on the line, and when  $d \geq 5$ , plus one

for the distance between the circles. Therefore

$$g_d(k) = \binom{k}{2} - T(k, t+1) + \left\lfloor \frac{k}{t} \right\rfloor + 1_{\{d>3\}}, \quad d \text{ odd}, \quad (2')$$

where  $1_{\{d>3\}}$  is the indicator function that is zero unless  $d > 3$  and one otherwise.

### 3. Lower bound on $f_d(k)$

For large  $n$  and fixed  $d \geq 3$ , let  $S$  be a set of  $n$  points in  $\mathbb{R}^d$ . Two ordered  $k$ -tuples of points  $S_k = (p_1, \dots, p_k)$  and  $S'_k = (p'_1, \dots, p'_k)$  are said to have the same *type* if

$$|p_i - p_j| = |p_g - p_h| \text{ if and only if } |p'_i - p'_j| = |p'_g - p'_h| \text{ for all } i, j, g, h.$$

Recalling that  $D(S_k)$  denotes the number of distinct distances in  $S_k$ , we clearly have  $D(S_k) = D(S'_k)$  for any two  $k$ -tuples  $S_k, S'_k$  having the same type. Let  $\mathbf{T} = \{T_1, \dots, T_k\}$  be a set of  $k$  triples, where  $T_i \subseteq S$ . We say that  $\mathbf{T}$  is *type invariant* if all  $k$ -tuples  $S'_k = (p'_1, \dots, p'_k)$  with  $p_i \in T_i$  ( $1 \leq i \leq k$ ) have the same type. If  $\mathbf{T}$  is type invariant, we define  $D(\mathbf{T}) = D(S_k)$ . We call  $S_k$  a *representative*  $k$ -tuple of  $\mathbf{T}$ . The role of type invariance is shown in the following lemma.

**Lemma 3.1.** *Let  $d, k, w$  be fixed integers, and fix  $\varepsilon > 0$ . Then there exists an integer  $n_0 = n_0(d, k, w, \varepsilon)$  with the following property. Any set  $S$  of  $n \geq n_0$  points in  $\mathbb{R}^d$  for which there are at least  $\varepsilon n^k$   $k$ -tuples that determine  $w$  distinct distances contains a type invariant set of  $k$  triples  $\mathbf{T} = \{T_1, \dots, T_k\}$ , with  $D(\mathbf{T}) = w$ .*

**Proof.** Let  $S$  satisfy the condition of the lemma, and let  $H$  denote the  $k$ -uniform hypergraph consisting of the  $k$ -tuples described. It follows from a well-known result of Erdős that we can divide  $S$  into disjoint parts  $V_1, \dots, V_k$  and find an  $\varepsilon' > 0$  so that there are at least  $\varepsilon' n^k$  hyperedges in  $H$  having precisely one point from each  $V_i$ . In fact  $\varepsilon' = (k!/k^k)\varepsilon$  will do. Let  $H'$  denote the subhypergraph consisting of these  $k$ -tuples. Since the total number of possible types of  $k$ -tuples is at most  $\binom{k}{2}^{\binom{k}{2}}$ , we can find an  $\varepsilon^* > 0$  so that at least  $\varepsilon^* n^k$   $k$ -tuples in  $H'$  have the same type. Let  $H^*$  denote the subhypergraph of  $H'$  consisting of these  $k$ -tuples. Now  $\varepsilon^*$  is independent of  $n$ . It follows from another well-known theorem of Erdős [4] that if  $n$  is sufficiently large, there is a system of triples  $T_i \subseteq V_i$ , such that every  $k$ -tuple with a point from each  $T_i$  is included in  $H^*$ . Therefore  $\mathbf{T} = \{T_1, \dots, T_k\}$  is a type invariant triple system with  $D(\mathbf{T}) = w$ .  $\square$

Given a type invariant triple system  $\mathbf{T}$ , we define an edge coloured graph  $G = G(\mathbf{T})$  as follows. The vertices of  $G$  are the  $k$  triples in  $\mathbf{T}$ . Let  $S_k = \{p_1, \dots, p_k\}$  be a representative  $k$ -tuple for  $\mathbf{T}$ . Then  $(T_i, T_j)$  is an edge of  $G$  whenever  $|p_i - p_j| = |p_g - p_h|$  for some  $\{g, h\} \neq \{i, j\}$ . Furthermore, edges are

given the same colour whenever their lengths are the same. Let  $\bar{G}$  denote the complement of  $G$ . It is immediate from the definitions that  $D(\mathbf{T})$  is equal to the number of edges in  $\bar{G}$  plus the number of edge colours. Each edge in  $G$  implies certain geometric constraints on the triples defining its endpoints. These are summarized in the following lemma.

**Lemma 3.2.** *Let  $(T_i, T_j)$  and  $(T_g, T_h)$  be monochromatic edges of the graph  $G = G(\mathbf{T})$  defined above.*

(i) *If  $i, j, g, h$  are all distinct, then  $T_i$  and  $T_j$  determine two circles  $C_i$  and  $C_j$  with common centre and lying in two orthogonal 2-flats.*

(ii) *If  $i, j, g$  are distinct and  $h = j$ , then either case (i) occurs with  $T_g$  lying on  $C_i$ , or  $T_j$  lies on a line  $l$  orthogonal to, and passing through the common centre of, circles  $C_i$  and  $C_g$  determined by  $T_i$  and  $T_g$ .  $C_i$  and  $C_g$  need not be orthogonal.*

We call a vertex  $T_i$  that is not isolated in  $G$  *linear* if its points lie on a line, and *circular* otherwise. Based on the above lemma, we have that  $G(\mathbf{T})$  satisfies the following combinatorial properties describing  $G(\mathbf{T})$ .

**Lemma 3.3.** *For  $d \geq 3$ , let  $t = \lceil d/2 \rceil$ .*

(i)  *$G(\mathbf{T})$  cannot contain  $K_{t+1}$  as a subgraph.*

(ii) *If  $d$  is odd then  $G(\mathbf{T})$  cannot contain a  $K_t$  in which all of the vertices are circular.*

(iii) *If  $T_i$  is linear, then either all edges of a given colour are incident on  $T_i$  or none are.*

**Proof.** (i) Suppose  $G = G(\mathbf{T})$  contained a  $K_{t+1}$ . Each edge colour in  $G$  occurs at least twice. Therefore by Lemma 3.2, each vertex of the  $K_{t+1}$  corresponds to some triple  $T_i$  that lies in a subspace orthogonal to the triples corresponding to each of the other  $t$  vertices. Further at most one of these vertices can be linear. Therefore the  $K_{t+1}$  spans  $2t + 1$  dimensions, a contradiction.

(ii) Arguing similarly to (i), the existence of such a  $K_t$  would require  $2t$  dimensions, a contradiction.

(iii) Suppose  $T_i$  is linear and edge  $(T_i, T_j)$  is red. If there is a red edge  $(T_g, T_h)$  where  $\{i, j\} \neq \{g, h\}$ , we can apply Lemma 3.2(i). But this contradicts the fact that  $T_i$  is linear.  $\square$

Finally, before proving the main lemma we need a couple of technical results that are contained in the following lemma.

**Lemma 3.4.** *For natural numbers  $k \geq t \geq 2$ :*

$$(i) \quad \sum_{i=0}^{t-1} \left\lfloor \frac{k-i}{t} \right\rfloor = k - t + 1.$$

$$(ii) \quad T(k, t+1) \geq T(k, t) + \left\lfloor \frac{k}{t} \right\rfloor.$$

**Proof.** (i) This is easily verified for  $k = t$ . Otherwise

$$\sum_{i=0}^{t-1} \left\lfloor \frac{k+1-i}{t} \right\rfloor - \sum_{i=0}^{t-1} \left\lfloor \frac{k-i}{t} \right\rfloor = \left\lfloor \frac{k+1}{t} \right\rfloor - \left\lfloor \frac{k+1-t}{t} \right\rfloor = 1.$$

(ii) Recall that  $T(k, t+1)$  counts the number of edges in a complete  $t$ -partite graph on  $k$  vertices with the vertices as evenly distributed as possible. We construct a complete  $(t-1)$ -partite graph with vertices as evenly distributed as possible and  $T(k, t)$  edges from this graph as follows: Choose a part with  $\lfloor k/t \rfloor$  vertices, and sequentially move each vertex to one of the other  $t-1$  parts that has minimum cardinality. The vertex moved is made adjacent to all vertices that are not in its new part. Since the cardinality of the new part is at least  $\lfloor k/t \rfloor$ , the number of edges in the graph goes down by at least one at each step. The result follows.  $\square$

We are now ready to prove the main lemma about type invariant triple systems.

**Lemma 3.5.** *For a type invariant triple system  $T$  containing  $k$  triples of points in  $\mathbb{R}^d$ ,  $d \geq 3$ ,*

$$D(T) \geq g_d(k).$$

**Proof.** Let  $t = \lceil d/2 \rceil$  and let  $G = G(T)$  be the edge coloured graph described above defined on  $T$ . By Lemma 3.3(i),  $G$  cannot contain a  $K_{t+1}$ . Therefore  $\bar{G}$ , the complement of  $G$ , contains at least  $\binom{k}{2} - T(k, t+1)$  edges. Recall that the number of distinct distances in  $T$  is the sum of the number of colours in  $G$  and the number of edges in its complement. If  $d$  is even we have from (1') that

$$D(T) \geq \binom{k}{2} - T(k, t+1) + 1 = g_d(k),$$

as required.

The case where  $d$  is odd is more difficult and we proceed by induction on  $k$ . We have trivially that  $D(T) \geq g_d(k)$  for  $k \leq t-1$ . Fix some  $k \geq t$  and assume inductively that  $D(T) \geq g_d(j)$  for  $j \leq k-1$ . We first suppose that  $G$  has no  $K_t$  as a subgraph. If  $d=3$  then  $G$  has no edges and all distances are distinct. If  $d \geq 5$ , then the complement  $\bar{G}$  has at least  $\binom{k}{2} - T(k, t)$  edges, so

$$D(T) \geq \binom{k}{2} - T(k, t) + 1 \geq \binom{k}{2} - T(k, t+1) + \left\lfloor \frac{k}{t} \right\rfloor + 1 = g_d(k),$$

where the second inequality follows from Lemma 3.4(ii).

We now assume that  $G$  contains a  $K_t$ , which by Lemma 3.3(ii) has at least one linear vertex, say  $T_i$ . If  $k=t$  we are done: this case is impossible for  $d=3$ , and for  $d \geq 5$   $G$  must have at least two colours, so  $D(T) \geq 2 = g_d(t)$ . If  $k=t+1$  then

$\bar{G}$  contains at least one edge (since there can be no  $K_{t+1}$ ), the edges of  $G$  require two colours if  $d > 3$  and one colour if  $d = 3$ , so  $D(\mathbf{T}) \geq g_d(t+1)$  as required. So we may assume  $k > t + 1$ . By Lemma 3.3(iii), there must be some colour, say red, for which all the red edges are incident on  $T_i$ . Since there can be no  $K_{t+1}$ , each of the  $k - t$  vertices of  $G$  not in the  $K_t$  must be non-adjacent to at least one vertex in the  $K_t$ . Consider deleting the  $t$  triples corresponding to the vertices of the  $K_t$  from the  $k$  triple system  $\mathbf{T}$  obtaining the  $k - t$  triple system  $\mathbf{T}'$ . Since  $\mathbf{T}'$  is also type invariant, we may apply the inductive hypothesis to it. Let  $G' = G(\mathbf{T}')$ . The number of colours in  $G'$  is at least one less than the number of colours in  $G$ . The number of edges in  $\bar{G}'$  is at least  $k - t$  less than the number of edges in  $\bar{G}$ . Therefore

$$\begin{aligned} D(\mathbf{T}) &\geq D(\mathbf{T}') + 1 + k - t \geq g_d(k - t) + 1 + k - t \\ &= g_d(k) + 1 + k - t - \sum_{i=0}^{t-1} \left\lfloor \frac{k-i}{t} \right\rfloor = g_d(k) \end{aligned}$$

as required. The first equation above comes from iterating Equation (2), the second follows from Lemma 3.4(i).  $\square$

We can now prove the main theorem.

**Theorem 3.6.** *For all  $d \geq 3$ ,  $f_d(k) = g_d(k)$ .*

**Proof.** In Section 2 we showed that  $f_d(k) \leq g_d(k)$ , so it remains to show that  $g_d(k)$  is also a lower bound. Let  $t = \lceil d/2 \rceil$ . Assume that there is an  $\varepsilon > 0$  for which one can find arbitrarily large sets of  $n$  points where at least  $\varepsilon n^k$  of the  $k$ -subsets determine  $w$  distinct distances. By Lemma 3.1, we can find a type invariant triple system  $\mathbf{T} = \{T_1, \dots, T_k\}$  which also determines  $w$  distinct distances. From Lemma 3.5 we have  $w \geq g_d(k)$ , completing the proof.  $\square$

#### 4. Results for $d = 2$

In this section we obtain some results of  $h^{i,k}(n)$ , the maximum number of  $k$ -element subsets  $S_k$  of a planar set of  $n$  points with the property that  $D(S_k) \leq i$ .

**Proposition 4.1.** *Let  $k \geq 3$ ,  $2 \leq i \leq k - 2$  be fixed and let  $n$  tend to infinity. Then:*

- (i)  $\Omega(n^{k-1} \log n) \leq h^{\binom{k}{2}-1,k}(n) \leq O(n^{k-2/3})$ ,
- (ii)  $\Omega(n^{k-1}) \leq h^{\binom{k}{2}-i,k}(n) \leq O(n^{k-1})$ .

**Proof.** (i) The number of isosceles triangles determined by the points of an  $n^{1/2}$  by  $n^{1/2}$  piece of the integer lattice is at least  $cn^2 \log n$ , for some positive constant  $c$ .

For each isosceles triangle we can pick  $k - 3$  other points arbitrarily, to obtain a  $k$ -element subset with at most  $\binom{k}{2} - 1$  distinct distances. This shows the lower bound. On the other hand, the number of those  $k$ -element subsets of an  $n$ -element set  $S$  which contain two element equidistant from a third one is at most

$$(\text{number of isosceles triangles in } S) \binom{n-3}{k-3} = O(n^{k-2/3}),$$

because the first term of this product is known to be  $O(n^{7/3})$  [6]. The number of those  $k$ -element subsets of  $S$  which contain two disjoint pairs determining the same distance, is at most

$$\binom{n-4}{k-4} \sum_{\Delta} \binom{m(s, \Delta)}{2},$$

where  $m(s, \Delta)$  denotes the number of point pairs in  $S$  determining distance  $\Delta$ . Thus,  $\sum_{\Delta} m(s, \Delta) = \binom{n}{2}$  and by [7] and [2],  $m(s, \Delta) \leq cn^{\frac{4}{3}}$  for every  $\Delta$ . This implies that the above expression cannot exceed

$$\binom{n-4}{k-4} \frac{\binom{n}{2}}{cn^{4/3}} \binom{cn^{4/3}}{2} = O(n^{k-2/3}),$$

proving the upper bound in (i). For part (ii) of the proposition, we record the fact that the number of 4-tuples consisting of two disjoint pairs of vertices determining the same distance is  $O(n^{10/3})$ .

(ii) For the lower bound, it suffices to consider  $i = k - 2$ . Let  $S$  be an  $n$ -element set consisting of a point  $p$  and  $n - 1$  points equidistant from  $p$ . Then any  $k$ -element subset of  $S$  which contains  $p$  determines at most  $\binom{k}{2} - k + 2$  distinct distances, giving the lower bound. For the upper bound it suffices to consider  $i = 2$ . Let us consider an  $n$ -element point set  $S$  in the plane, and let  $S_k$  be a  $k$ -element subset of  $S$  that determines at most  $\binom{k}{2} - 2$  distinct distances. Let  $G_k$  be an edge coloured graph with vertex set  $V(G_k) = S_k = \{p_1, \dots, p_k\}$ , two vertices  $p_a$  and  $p_b$  being joined by an edge if and only if  $|p_a - p_b| = |p_c - p_d|$  for some  $\{c, d\} \neq \{a, b\}$ . Since  $S_k$  determines  $\binom{k}{2} - 2$  distinct distances, colours red and blue suffice. We consider five cases.

*Case 1:  $G_k$  contains three independent monochromatic edges.*

We proceed as in part (i) of the proposition. The number of such  $k$ -element subsets is at most

$$\binom{n-6}{k-6} \sum_{\Delta} \binom{m(s, \Delta)}{3} \leq \binom{n-6}{k-6} \frac{\binom{n}{2}}{cn^{4/3}} \binom{cn^{4/3}}{3} = O(n^{k-1}).$$

*Case 2:  $G_k$  contains disjoint red and blue isosceles triangles.*

The number of 6-tuples determining two disjoint isosceles triangles is at most the square of the total number of isosceles triangles determined by the set of points, which is  $O(n^{14/3})$ . Thus the number of such  $k$ -element subsets is at most  $O(n^{k-1})$ .

*Case 3:  $G_k$  contains a (say) red isosceles triangle and two blue edges, which are all mutually disjoint.*

The number of such 7-tuples is at most the number of isosceles triangles times the number of 4-tuples determining two monochromatic edges. From part (i) of the proposition, this is at most  $O(n^{7/3})O(n^{10/3}) = O(n^6)$ . Again the number of  $k$ -element subsets for this case is at most  $O(n^{k-1})$ .

*Case 4:  $G_k$  contains two red edges and two blue edges, which are all mutually disjoint.*

The number of such 8-tuples is at most  $O(n^{10/3})O(n^{10/3}) = O(n^7)$ , and the number of  $k$ -element subsets for this case is at most  $O(n^{k-1})$ .

*Case 5: There is a point  $p_a$  in  $G_k$  that is (a) incident to 3 edges of the same colour, or (b) incident to at least one red edge and at least one blue edge, or (c) incident to 2 edges of the same colour and  $G_k$  is monochromatic.*

We want to assign to each such  $k$ -element subset  $S_k \subseteq S$  a  $(k-1)$ -element subset  $S'_k \subseteq S_k$  so that every  $(k-1)$ -tuple is assigned to only a bounded number of  $k$ -tuples. This can be done as follows. Set  $S'_k = S_k - \{p_a\}$ . Given  $S'_k$  and  $G_k$ , the location of  $p_a$  is pretty much determined. If  $p_a$  has degree at least 3 in  $G_k$  then its position is uniquely determined. Otherwise there are at most 2 possible locations for  $p_a$ . Now for each  $(k-1)$ -tuple  $S' \subseteq S$  there are at most  $c_1 k^6$  different  $k$ -tuples  $S_k$  with  $S'_k = S'$ , for some positive constant  $c_1$ . To see this, note that the position of  $p_a$  is determined (up to a constant number of locations) by three points in Case 5(a), at most six points in Case 5(b), and at most four points in Case 5(c). This shows that the number of  $k$ -tuples satisfying the condition of Case 4 is at most  $c_1 k^6 \binom{n}{k-1} = O(n^{k-1})$ .

Cases 1–5 are exhaustive, so we have shown that the number of  $k$ -tuples determining at most  $\binom{k}{2} - 2$  distinct distances is at most  $O(n^{k-1})$  completing the proof of the proposition.  $\square$

Until now  $k$  was always assumed to be fixed as  $n$  tended to infinity. Next we investigate how fast  $k$  can grow with  $n$  so that it still remains true that almost all (in the sense defined in the introduction)  $k$ -element subsets of any set of  $n$  points in the plane determine  $\binom{k}{2}$  distinct distances.

**Theorem 4.2.** *Let  $n$  tend to infinity,  $k = o(n^{1/7})$ . Then almost all  $k$ -element subsets of a set  $S$  of  $n$  points in the plane determine  $\binom{k}{2}$  distinct distances.*

**Proof.** We prove the equivalent statement that there are at least  $(1 - o(1))n^k$  ordered  $k$ -tuples that determine distinct distances. Let  $S$  be any set of  $n$  points in the plane. A point  $p \in S$  is called *central* if there is a circle around  $p$  passing

through at least  $n^{3/7}$  elements of  $S$ . According to a theorem of Clarkson et al. [2] the maximum number of incidences among  $n$  points and  $m$  circles in the plane is  $O(n^{3/5}m^{4/5} + n + m)$ . Hence, letting  $m$  denote the number of central points of  $S$ , we obtain

$$mn^{3/7} = O(n^{3/5}m^{4/5} + n + m)$$

and so  $m = O(n^{6/7})$ . A straight line  $l$  is called *rich* if  $l$  contains at least  $n^{1/2}$  elements of  $S$ . It is easy to see that the number of rich lines  $r = O(n^{1/2})$ .

Let us define a large number of ordered  $k$ -tuples of  $S$  by the following procedure. Pick any noncentral point  $p_1 \in S$ . If  $p_1, p_2, \dots, p_i$  have already been determined for some  $i < k$  so that all distances  $d_1, d_2, \dots, d_{\binom{i}{2}}$  induced by them are different, then we choose  $p_{i+1}$  to be any point of  $S$  satisfying the following properties:

- (i)  $p_{i+1}$  is not central;
- (ii)  $|p_{i+1} - p_a| \neq d_b$  ( $a \leq i, b \leq \binom{i}{2}$ );
- (iii)  $p_{i+1}$  is not the mirror image of  $p_a$  with respect to a rich line  $l$  ( $a \leq i$ );
- (iv)  $p_{i+1}$  does not lie on the perpendicular bisector of  $p_a$  and  $p_{a'}$  ( $a, a' \leq i$ ).

Let  $n^{(i)}, n^{(ii)}, n^{(iii)}$ , and  $n^{(iv)}$  denote the number of points in  $S$  violating property (i)–(iv), respectively. Obviously, we have  $n^{(i)} \leq m = O(n^{6/7})$ , and  $n^{(iii)} \leq ir = iO(n^{1/2})$ . The bound

$$n^{(ii)} \leq i \binom{i}{2} n^{3/7}$$

follows from the fact that no  $p_a$  is central, thus the circle of radius  $d_b$  around  $p_a$  passes through at most  $n^{3/7}$  points of  $S$ . Finally

$$n^{(iv)} \leq \binom{i}{2} n^{1/2}$$

because the perpendicular bisector of  $p_a$  and  $p_{a'}$  cannot be rich.

Thus the number of different ways we can define an ordered  $k$ -tuple  $p_1, \dots, p_k$  by the above procedure is at least

$$\prod_{0 \leq i \leq k} \left( n - i - O(n^{6/7}) - i \binom{i}{2} n^{3/7} - iO(n^{1/2}) - \binom{i}{2} n^{1/2} \right) \geq n^k e^{-ck/n^{1/7}} = (1 - o(1))n^k,$$

provided that  $k = o(n^{1/7})$ , and the result follows.  $\square$

It is easy to see that if we choose  $n$  equidistant points along a line and let  $k = \Omega(n^{1/4})$ , then a positive percentage of all  $k$ -tuples determine fewer than  $\binom{k}{2}$  distinct distances. A simple calculation along the above lines shows that this bound on  $k$  cannot be improved, as the following holds.

**Proposition 4.3.** *Let  $n$  tend to infinity and let  $k = o(n^{1/4})$ . Then almost all  $k$ -element subsets of a set of  $k$  points on a line determine  $\binom{k}{2}$  distinct distances.*
