Intermediate representations

front end produces an intermediate representation (IR) for the program.

optimizer transforms the code in IR form into an equivalent program that may run more efficiently.

back end transforms the code in IR form into native code for the target machine

The IR encodes knowledge that the compiler has derived about the source program.

Intermediate representations

Advantages
- compiler can make multiple passes over program
- break the compiler into manageable pieces
- support multiple languages and architectures using multiple front & back ends
- enables machine-independent optimization

Desirable properties
- easy & inexpensive to generate and manipulate
- contains sufficient information

Examples
- abstract syntax tree (AST)
- directed acyclic graph (DAG)
- control flow graph (CFG)
- three address code
- stack code

Abstract syntax tree

An abstract syntax tree (AST) is the procedure’s parse tree with the nodes for most non-terminal symbols removed.

This represents “x - 2 * y”.

For ease of manipulation, can use a linearized (operator) form of the tree.

x 2 y * - in postfix form.
Directed acyclic graph

A directed acyclic graph (DAG) is an AST with a unique node for each value.

\[
\begin{align*}
&\text{<id.x>} \\
\text{\downarrow} &\text{<id.x>} \quad + \\
&\text{<id.x>} \quad \text{sin} \\
\text{\downarrow} &\text{<id.y>} \quad \times \\
&\text{<num.2>} \quad \text{<id.x>} \quad \text{/} \\
&x \leftarrow 2 \times y + \sin(2 \times x) \\
z \leftarrow x / 2
\end{align*}
\]

Control flow graph

The control flow graph (CFG) models the transfers of control in the procedure.

- nodes in the graph are \textit{basic blocks}
- edges in the graph represent control flow
- loops, if-then-else, case, goto

Example

\[
\begin{align*}
\text{if (x=y)} \\
&\text{then s1} \\
&\text{else s2} \\
&\text{s3}
\end{align*}
\]

becomes

\[
\begin{align*}
\text{x=y} \\
\text{s1} \\
\text{s2} \\
\text{s3}
\end{align*}
\]

Three address code

Three address code generally allow statements of the form:

\[
x \leftarrow y \ op \ z
\]

with a single operator and, at most, three names.

Complex expressions like

\[
x - 2 \times y
\]

are simplified to

\[
t1 \leftarrow 2 \times y \\
t2 \leftarrow x - t1
\]

Advantages

- compact form (direct naming)
- names for intermediate values

Register transfer language (RTL)

- only load/store instructions access memory
- all other operands are registers
- version of three address code for RISC

Three address code

Typical statement types

1. assignments \( x \leftarrow y \ op \ z \)
2. assignments \( x \leftarrow op \ y \)
3. assignments \( x \leftarrow y[i] \)
4. assignments \( x \leftarrow y \)
5. branches \( \text{goto L} \)
6. conditional branches \( \text{if x relop y goto L} \)
7. procedure calls \( \text{param x and call p} \)
8. address and pointer assignments

Can represent three address code using \textit{quadruples}

\[
\begin{align*}
&x - 2 \times y \\
&(1) \quad \text{load} \quad t1 \quad y \\
&(2) \quad \text{load} \quad t2 \quad 2 \\
&(3) \quad \text{mult} \quad t3 \quad t2 \quad t1 \\
&(4) \quad \text{load} \quad t4 \quad x \\
&(5) \quad \text{sub} \quad t5 \quad t4 \quad t2
\end{align*}
\]
**Stack machine code**

Can simplify IR by assuming implicit stack

Example

\[ z = x - 2 \times y \]

becomes

push \( x \)
push \( 2 \)
push \( y \)
multiply
subtract
store \( z \)

**Advantages**

- compact form
- introduced names are implicit, not explicit
- simple to generate and execute code

**Disadvantages**

- processors operate on registers, not stacks
- difficult to reuse values on stack

---

**Virtual machines**

Can interpret IR using “virtual machine”

**Examples**

- P-code for Pascal
- postscript for display devices
- Java byte code for everywhere

**Result**

- easy & portable
- much slower

**Just-in-time compilation (JIT)**

- begin interpreting IR
- find performance critical section(s)
- compile section(s) to native code
- ...or just compile entire program
- compilation time becomes execution time

---

**Intermediate representations**

But this isn’t the whole story

**Symbol table:**

- identifiers, procedures
- size, type, location
- lexical nesting depth

**Constant table:**

- representation, type
- storage class, offset(s)

**Storage map:**

- storage layout
- overlap information
- (virtual) register assignments

---

**Java virtual machine (JVM)**

The JVM consists of four parts

**Memory**

- stack (for function call frames)
- heap (for dynamically allocated memory)
- constant pool (shared constant data)
- code segment (instructions of class files)

**Registers**

- stack pointer (SP), local stack pointer (LSP), program counter (PC)

**Condition codes**

- stores result of last conditional instruction

**Execution unit**

1. reads current JVM instruction
2. change state of virtual machine
3. increment PC (modify if call, branch)
### Java byte codes

#### Arithmetic instructions

- `ineg` \[\ldots :i\] \[\ldots :-i\]
- `iadd` \[\ldots :i1,i2\] \[\ldots :i1+i2\]
- `isub` \[\ldots :i1,i2\] \[\ldots :i1-i2\]
- `imul` \[\ldots :i1,i2\] \[\ldots :i1*i2\]
- `idiv` \[\ldots :i1,i2\] \[\ldots :i1/i2\]

#### Direct instructions

- `iinc k a` \[\ldots \] \[\ldots :local[k]+a\]

#### Branch instructions

- `goto L` \[\ldots \] \[\ldots :branch to L\]
- `ifeq L` \[\ldots :i\] \[\ldots :branch if i = 0\]
- `ifne L` \[\ldots :i\] \[\ldots :branch if i != 0\]
- `ifnonnull L` \[\ldots :o\] \[\ldots :branch if o != null\]
- `if_icmpeq L` \[\ldots :i1,i2\] \[\ldots :branch if i1 = i2\]
- `if_icmpne L` \[\ldots :i1,i2\] \[\ldots :branch if i1 != i2\]
- `if_icmpgt L` \[\ldots :i1,i2\] \[\ldots :branch if i1 > i2\]
- `if_icmplt L` \[\ldots :i1,i2\] \[\ldots :branch if i1 < i2\]
- `if_acmpeq L` \[\ldots :o1,o2\] \[\ldots :branch if o1 = o2\]
- `if_acmpne L` \[\ldots :o1,o2\] \[\ldots :branch if o1 != o2\]

### Java bytecode interpreter

```java
pc = code.start
while (true) {
    new_pc = pc + inst_len(code[pc]);
    switch (opcode(code[pc])) {
    case iconst_0:
        push(0); break;
    case iconst_1:
        push(1); break;
    case iload:
        t ← pop();
        local[code[pc+1]] ← t; break;
    case iadd:
        t1 ← pop(); t2 ← pop();
        push(t1 + t2); break;
    case ifeq:
        t ← pop();
        if (t = 0) new_pc = code[pc+1]; break;
    }
    pc ← new_pc;
}
```
