State Pattern
Apr. 19, 2007

An Example

Let’s create a drawing program that will have toolbar buttons for Pick, Rectangle, Fill, Circle and Clear. Each one of the tool buttons does something rather different when it is selected and you click or drag your mouse across the screen. For example,
- If the Pick button is selected, clicking inside a drawing element should cause it to be highlighted or appear with “handles.”
- If the mouse is dragged and a drawing element is already selected, the element should move on the screen.
- If the Rect button is selected, clicking on the screen should cause a new rectangle drawing element to be created.

Thus, the state of the graphical editor affects the behavior the program should exhibit.

A Possible Solution

We might design our program with a Mediator managing the actions of 5 command buttons.
However…

- This initial design puts the entire burden of maintaining the state of the program on the Mediator, and we know that the main purpose of a Mediator is to coordinate activities between various controls, such as the buttons.
- Keeping the state of the buttons and the desired mouse activity inside the Mediator can make it unduly complicated as well as leading to a set of if or switch tests which make the program difficult to read and maintain.
- Further, this set of conditional statements might have to be repeated for each action the Mediator interprets, such as mouseUp, mouseDrag, rightClick and so forth.
- This makes the program very hard to read and maintain.

New Design Strategy

- There are some common threads among several of the actions we should explore.
  - Four of them use the mouse click event to cause actions.
  - One uses the mouse drag event to cause an action.
- Thus, we really want to create a system that can help us redirect these events based on which button is currently selected.

The State Pattern

- The State pattern is used when you want to have an enclosing class switch between a number of related contained classes, and pass method calls on to the current contained class.

Let's Use a State Object

- We’ll need a State object that handles mouse activities.

```java
class State {
    public void mouseDown(int x, int y) {}
    public void mouseUp(int x, int y) {}
    public void mouseDrag(int x, int y) {}
}
```
- Since none of the cases we’ve described need all of these events, we’ll give our base class empty methods rather than creating an abstract base class.
- Then we’ll create 4 derived State classes for Pick, Rect, Circle and Fill and put instances of all of them inside a StateManager class which sets the current state and executes methods on that state object.
The StateManager

- The StateManager class is referred to as a Context.

RectState

- A typical State object simply overrides those event methods that it must handle specially.
- For example, this is the complete Rectangle state object.

```java
public class RectState extends State {
    private Mediator med; // save the Mediator
    public RectState(Mediator md) {
        med = md;
    }
    // --------------------------------------
    // create a new Rectangle where mouse clicks
    public void mouseDown(int x, int y) {
        med.addDrawing(new visRectangle(x, y));
    }
}
```

Circle

- The RectState object simply tells the Mediator to add a rectangle drawing to the drawing list.
- Similarly, the Circle state object tells the Mediator to add a circle to the drawing list.

```java
public class CircleState extends State {
    private Mediator med; // save Mediator
    public CircleState(Mediator md) {
        med = md;
    }
    // --------------------------------------
    // draw circle where mouse clicks
    public void mouseDown(int x, int y) {
        med.addDrawing(new visCircle(x, y));
    }
}
```

The Fill Button

- The only tricky button is the Fill button, because we have defined two actions for it.
  - If an object is already selected, fill it.
  - If the mouse is clicked inside an object, fill that one.
- In order to carry out these tasks, we need to add the select method to our base State class.
- This method is called when each tool button is selected.

```java
public class State {
    public void mouseDown(int x, int y){}
    public void mouseUp(int x, int y){}
    public void mouseDrag(int x, int y){}
    public void select(Drawing d, Color c){}
}
```
The Drawing argument is either the currently selected Drawing or null if none is selected, and the color is the current fill color.

In this simple program, we have arbitrarily set the fill color to red.

Switching Between States

Now that we have defined how each state behaves when mouse events are sent to it, we need to discuss how the StateManager switches between states; we simply set the currentState variable to the state is indicated by the button that is selected.

Note...

This version of the StateManager, we create an instance of each state during the constructor and copy the correct one into the state variable when the set methods are called.

It would also be possible to use a Factory to create these states on demand.

This might be advisable if there are a large number of states which each consume a fair number of resources.
The Rest of the Code…

- The remainder of the state manager code simply calls the methods of whichever state object is current.
- This is the critical piece -- there is no conditional testing.
- Instead, the correct state is already in place and its methods are ready to be called.

```java
public void mouseDown(int x, int y) {
    currentState.mouseDown(x, y);
}
public void mouseUp(int x, int y) {
    currentState.mouseUp(x, y);
}
public void mouseDrag(int x, int y) {
    currentState.mouseDrag(x, y);
}
public void select(Drawing d, Color c) {
    currentState.select(d, c);
}
```

Mediator and State Manager Interaction

- It is clearer to separate the state management from the Mediator’s button and mouse event management.
- The Mediator is the critical class, however, since it tells the StateManager when the current program state changes.
- The beginning part of the Mediator illustrates how this state change takes place.

Coding the Interaction

```java
public Mediator() {
    startRect = false;
    dSelected = false;
    drawings = new Vector();
    undoList = new Vector();
    stMgr = new StateManager(this);
}
```

Concluding Remarks

- The State pattern localizes state-specific behavior in an individual class for each state, and puts all the behavior for that state in a single object.
- It eliminates the necessity for a set of long, look-alike conditional statements scattered through the program’s code.
- It makes transition explicit. Rather than having a constant that specifies which state the program is in, and that may not always be checked correctly, this makes the change explicit by copying one of the states to the state variable.
- State objects can be shared if they have no instance variables. Here only the Fill object has instance variables, and that color could easily be made an argument instead.
- This approach generates a number of small class objects, but in the process, simplifies and clarifies the program.
- In Java, all of the States must inherit from a common base class, and they must all have common methods, although some of those methods can be empty. In other languages, the states can be implemented by function pointers with much less type checking, and, of course, greater chance of error.
Good Question to Consider!

- Rewrite the StateManager to use a Factory pattern to produce the states on demand.
