Problem Set 6

Due at beginning of class on Dec. 13

- 1. We saw in class that one suggestion for signing using RSA (with public exponent 3) is to first *encode* the message and then sign using "textbook" RSA. More precisely, the public key consists of a modulus N for which $gcd(3, \varphi(N)) = 1$. The secret key consists of an exponent d such that $3d = 1 \mod \varphi(N)$. To sign message m, compute $(enc(m))^d \mod N$, where enc is some deterministic, publicly-known encoding procedure.
 - (a) How is signature verification performed in this scheme?

We showed in class that setting enc(m) = H(m) was secure when H was modeled as a random oracle. Here, we investigate other possibilities for enc. Assume |N| = 1024.

- (b) Consider the function $enc(m) = 0|m|0^{99}$ (where |m| = 924 and $m \neq 0^{924}$). Show that this is insecure. (*Hint*: ask for one signature and then forge a signature on some different message.)
- (c) For graduate students, or for extra credit. Consider the function enc(m) = 0m|0m (where |m| = 511) and $m \neq 0^{511}$). Show that this is insecure. (*Hint*: ask for one signature and then forge a signature on some different message.)
- 2. We improve (slightly) on the Lamport one-time signature scheme we gave in class. Recall that the Lamport scheme requires a public key consisting of 2ℓ elements in order to sign messages ℓ bits long. Since signing ℓ -bit messages can also be viewed as signing one message out of 2^{ℓ} possible messages, we can view the efficiency of the Lamport scheme in the following equivalent way: if there are n elements in the public key, we can sign one message out of $2^{n/2}$ possible messages.

We now show one way to improve this. Consider the following scheme which allows signing one message out of 6 possible messages: the public key consists of four elements (y_1, y_2, y_3, y_4) . The secret key consists of their inverses $(x_1 = f^{-1}(y_1), \ldots)$. We assume the 6 possible messages are ordered in advance in some publicly known way (i.e., lexicographically). To sign message 1, send the pair (x_1, x_2) ; to sign message 2, send the pair (x_1, x_3) ; ...; to sign message 6, send the pair (x_3, x_4) . Each signature consists of a pair of elements. Verification is done in the obvious way.

- (a) Prove the security of the above scheme for signing one of a possible 6 messages. How does the security reduction you obtain here compare to what was obtained in class for the Lamport scheme?
- (b) Sketch the generalization of the above scheme for when you have n elements in the public key (no proof of security is necessary).

- (c) What is the complexity of this generalization? In other words, given a public key containing n elements, how large is the space of possible messages you can sign? Try to generalize the scheme so as to obtain the best possible result.
- 3. In class we have mentioned three kinds of hash functions: collision-resistant hash functions, universal one-way hash functions, and random oracles. Here, we investigate the relationship among these. Let $H: \{0,1\}^{10k} \to \{0,1\}^k$.
 - (a) Show that if H is (t, ϵ) -collision resistant then it is also (t, ϵ) -universal one-way.
 - (b) Show that if H is a random oracle, then H is (t, ϵ) -collision resistant. Express ϵ in terms of the output length k.
 - (c) For graduate students, or for extra credit. Show that H can be universal one-way without being collision-resistant. Namely, give an *explicit* construction of a function which is (t, ϵ) -universal one-way (for some small ϵ) but not (t, 1/2)-collision resistant. For your construction, you may assume a collision-resistant hash function H' and/or a random oracle. You may give convincing arguments instead of rigorous proofs.
