

# Programming Project: Basic Pipelining

## CMSC411 Summer 2011

**Due: 11:59:59 PM Friday, October 28, 2011 (plus 48 hour grace period)**

In this assignment, you will become familiar with how a basic 5-stage pipeline works. You will be given a simulator that models an unpipelined processor that implements a small MIPS-like instruction set. Your assignment is to create a cycle-accurate simulator of a pipelined version of this processor. Your simulator will perform data forwarding, a simple branch prediction scheme, and the pipeline interlocks to stall the pipeline when necessary. You will be using accounts on the grace cluster. If you don't have one, go to the course webpage and click on the link to get one. Project questions will be answered on the cs forum (<http://forum.cs.umd.edu>).

### 1 Files

All the files you need, plus some extra data files can be found in the directory `mips-pipe` on my course pages. This archive contains the starter files for this project. `asm.c` is an assembler for the reduced MIPS ISA which your simulator will implement (more about the assembler and the ISA later). `mips-small.c` is the C source file for a fully functional *unpipelined* simulator. `mips-small-pipe.c` is a C source code template that has some data structures and routines you will need for your *pipelined* simulator. You can use this template to get started on the assignment. `mips-small-pipe.h` is a header file included by `mips-small-pipe.c`, and `Makefile` is a unix make file which will produce the binaries `asm`, `sim`, and `sim-pipe` from the source files, `asm.c`, `mips-small.c`, and `mips-small-pipe.c`, respectively.

In the remaining files, we have provided two example assembly programs. `simple.s` performs an arithmetic operation and `mult.s` multiplies two numbers. `simple.output` is the result of running `simple.s` through our pipelined simulator, and can be used to verify your simulator's output.

### 2 A Scaled-Down MIPS ISA

You will be simulating the MIPS ISA from Hennessy & Patterson, with some key differences. First, instead of a 64-bit architecture, you will implement a 32-bit architecture. In other words, all registers and data paths are 32 bits wide, and all instructions will operate on 32-bit operands. Second, to keep your simulator simple, you will only be required to support a scaled-down version of the MIPS ISA consisting of 11 instructions. These instructions, along with their encoding, are given in Table 1. We will adhere to the MIPS instruction formats presented in Figure B.27 of Hennessy & Patterson, with the exception that there is no "shamt" field in the R-type format, and instead the "func" field is 11-bits wide. Finally, although all immediate values in branch and jump instructions are left-shifted by 2, your BEQZ instruction **SHOULD NOT** perform the left shift.

Notice that all the instructions in Table 1 except for one exist in the normal MIPS ISA. These instructions behave exactly as described in the text (except they are 32-bit versions rather than 64-bit versions). The instruction we've added is "HALT." As its name implies, when your simulator executes a HALT instruction, it should terminate the simulation. For more information about MIPS, consult the MIPS Language Section of appendix B of Hennessy & Patterson.

Name	Format Type	Opcode	Func
LW	I-type	0x23	
SW	I-type	0x2B	
BEQZ	I-type	0x4	
ADDI	I-type	0x8	
ADD	R-type	0x0	0x20
SUB	R-type	0x0	0x22
SLL	R-type	0x0	0x4
SRL	R-type	0x0	0x6
AND	R-type	0x0	0x24
OR	R-type	0x0	0x25
HALT	J-type	0x3F	

**Table 1. Instruction encodings for a reduced MIPS ISA.**

### 3 asm: An Assembler for the Reduced MIPS ISA

We have provided an assembler, `asm.c`, so that you can assemble programs for your simulator. The `asm.c` file is fully functional, and you will not need to make any modifications to this file. Simply use the `Makefile` to make the binary `asm` from the `asm.c` source file.

The format for assembly programs is very simple. A valid assembly program is an ASCII file in which each line of the file represents a single instruction, or a data constant. The format for a line of assembly code is:

```
label<tab>instruction<tab>field0<tab>field1<tab>field2<tab>comments
```

The leftmost field on a line is the label field which indicates a symbolic address. Valid labels contain a maximum of 6 characters and can consist of letters and numbers. The label is optional (the tab following the label field is not). After the optional label is a tab. Then follows the instruction field, where the instruction can be any of the assembly-language mnemonics listed in Table 1. After another tab comes a series of fields. All fields are given as **decimal** numbers. The number of fields depends on the instruction. The following describes the instructions and how they are specified in assembly code:

```
lw   rd    rs1    imm    Reg[rd] <- Mem[Reg[rs1] + imm]
sw   rd    rs1    imm    Reg[rd] -> Mem[Reg[rs1] + imm]
beqz rd    rs1    imm    if (Reg[rs1] == 0) PC <- PC+4+imm
addi rd    rs1    imm    Reg[rd] <- Reg[rs1] + imm
add  rd    rs1    rs2    Reg[rd] <- Reg[rs1] + Reg[rs2]
sub  rd    rs1    rs2    Reg[rd] <- Reg[rs1] - Reg[rs2]
sll  rd    rs1    rs2    Reg[rd] <- Reg[rs1] << Reg[rs2]
srl  rd    rs1    rs2    Reg[rd] <- Reg[rs1] >> Reg[rs2]
and  rd    rs1    rs2    Reg[rd] <- Reg[rs1] & Reg[rs2]
or   rd    rs1    rs2    Reg[rd] <- Reg[rs1] | Reg[rs2]
halt                                stop simulation
```

Note that in the case of the `beqz` instruction, PC-relative addressing is used (and again, your simulator should not perform the left-shift when computing the PC-relative branch target). For the `lw`, `sw`, and `beqz` instructions, the `imm` field can either be a decimal value, or a label can be used. In the case of a label, the assembler performs a different action depending on whether the instruction is a `lw` / `sw` instruction, or a `beqz` instruction. For `lw` and `sw` instructions, the assembler inserts the absolute address corresponding to the label. For `beqz` instructions, the assembler computes a PC-relative offset with respect to the label.

After the last field is another tab, then any comments. The comments end at the end of the line.

In addition to instructions, lines of assembly code can also include directives for the assembler. The only directive we will use is `.fill`. The `.fill` directive tells the assembler to put a number into the place where the instruction would normally be stored. The `.fill` directive uses one field, which can be either

a numeric value or a symbolic address. For example, “.fill 32” puts the value 32 where the instruction would normally be stored. In the following example, “.fill start” will store the value 8, because the label “start” refers to address 8 (remember that the MIPS architecture uses byte addresses).

```

        addi    1      0      5      load reg1 with 5
        addi    2      0     -1     load reg2 with -1
start   add     1      1      2     decrement reg1
        lw     3      0     var1   loads reg3 with value stored in var1
        addi    3      3     -1     decrement reg3
        sw     3      0     var1   put reg3 back (thus var1 is decremented)
        beqz   0      1     done   goto done when reg1==0
        beqz   0      0     start  back to start
        add    0      0      0
done    halt
        .fill   start                    will contain start address (8)
var1    .fill   32                       Declare a variable, initialized to 32

```

Try taking the above example and running the assembler on it. Enter the above assembly code into a file called “ex.s”. Then type “asm ex.s ex.out”. The assembler will generate a file “ex.out” which should contain:

```

(address 0x0): 20010005
(address 0x4): 2002ffff
(address 0x8): 00220820
(address 0xc): 8c03002c
(address 0x10): 2063ffff
(address 0x14): ac03002c
(address 0x18): 10200008
(address 0x1c): 1000ffe8
(address 0x20): 00000020
(address 0x24): fc000000
(address 0x28): 00000008
(address 0x2c): 00000020

```

The assembler assumes that all programs will be loaded into memory beginning at address 0x0.

## 4 Simulator without Pipelining

As described above, we have provided you with a simulator that simulates the same ISA, but which is not cycle accurate because it does not account for pipelining. The source code for this simulator is in `mips-small.c`. You can use this simulator to develop assembly language programs prior to getting the pipelined simulator working.

If you haven’t done so already, build the unpipelined simulator by typing “`make sim`” in the directory where you’ve copied the files we have provided. This will produce an executable `sim` which you can run. Try running this simulator on the program we have provided, `mult.s`. This program multiplies two numbers, specified in memory at the labels `mcand` and `mplier`, and stores the result at the label `answer`. Be sure to assemble the program before running the simulator. The sequence of commands you should give are:

```

make sim
asm mult.s mult.out
sim mult.out

```

When you run the simulator, a ton of messages will spew onto your terminal. The simulator we have provided dumps the state of the machine (including the contents of registers and memory) at every simulated cycle. You can examine this output to see what the simulator is doing. To put these messages in a file so

that you can actually read them, redirect the output of the simulator to a file by saying “`sim mult.out > sim.output`”. Your pipelined simulator will spew similar messages, except it will also include the state of pipeline registers. The output of your pipelined simulator will be compared to the correct output to grade your project.

In addition to using the unpipelined simulator to develop assembly programs, you should also look at the code in `mips-small.c`. The code is very simple, but you should make sure you understand it before moving on to building the pipelined simulator.

## 5 Assignment

Your assignment is to build a cycle-accurate simulator that accounts for pipelining. We have provided some code to get you started in `mips-small-pipe.c` and `mips-small-pipe.h`. This code serves two purposes: it will make your life a bit easier since you won't have to write the whole simulator from scratch, and it is meant to enforce some coding disciplines that ensure you actually simulate the details of the processor pipeline in a manner that we can grade.

The following sections describe the assignment in greater detail.

### 5.1 Simulate Pipelining

You will be simulating the basic MIPS pipeline depicted in Figure A.18 of Hennessy & Patterson. We have provided pipeline register data structures specified in the file, `mips-small-pipe.h`. To enforce an implementation of your simulator that simulates pipelining, you are required to use these structures in their unmodified form. In other words, each cycle simulated by your simulator must produce the correct values for all the fields in the pipeline register data structures.

```
typedef struct IFIDStruct {
    int instr;
    int pcPlus1;
} IFID_t;
```

```
typedef struct IDEXStruct {
    int instr;
    int pcPlus1;
    int readRegA;
    int readRegB;
    int offset;
} IDEX_t;
```

```
typedef struct EXMEMStruct {
    int instr;
    int aluResult;
    int readRegB;
} EXMEM_t;
```

```
typedef struct MEMWBStruct {
    int instr;
    int writeData;
} MEMWB_t;
```

```
typedef struct WBENDStruct {
    int instr;
    int writeData;
} WBEND_t;
```

```

typedef struct stateStruct {
    int pc;
    int instrMem[MAXMEMORY];
    int dataMem[MAXMEMORY];
    int reg[NUMREGS];
    int numMemory;
    IFID_t IFID;
    IDEX_t IDEX;
    EXMEM_t EXMEM;
    MEMWB_t MEMWB;
    WBEND_t WBEND;
    int cycles; /* number of cycles run so far */
} state_t, *Pstate;

```

There are three small modifications in the above pipeline register data structures as compared with Figure A.18 in Hennessy & Patterson. First, we don't latch the "branch taken" signal in the EXMEM register. Instead, when your simulator computes the direction of the branch in the execute stage, you can directly modify the PC register from the execute stage. Second, the MUX in the WB stage has been moved to the MEM stage. Therefore, the MEMWB pipeline registers only latch two values, `instr` and `writeData`, instead of three values as indicated by Figure A.18 in the text. Finally, we have added an extra pipeline register after the WB stage. Instead of communicating internally through the register file, your simulator will always forward from the pipeline registers. For instance, in Figure A.7 of the text, there is a communication path from the DADD instruction to the OR instruction internally through the register file (this is achieved by writing the register file on the first half of the clock cycle, and reading the register file on the second half of the clock cycle). In your simulator, this register communication will be replaced by forwarding between the WBEND pipeline registers to the execute stage of the OR instruction in cycle CC6.

As mentioned above, your simulator must produce all the values for the pipeline register data structures on a cycle-by-cycle basis. In addition, your simulator must also use the following simulator loop code (which we have provided):

```

while (1) {

    printState(state);

    /* copy everything so all we have to do is make changes.
       (this is primarily for the memory and reg arrays) */
    memcpy(&new, state, sizeof(state_t));

    new.cycles++;

    /* ----- IF stage ----- */
    /* ----- ID stage ----- */
    /* ----- EX stage ----- */
    /* ----- MEM stage ----- */
    /* ----- WB stage ----- */

    /* transfer new state into current state */
    memcpy(state, &new, sizeof(state_t));
}

```

You will insert the necessary code between the comments that perform the functions at each pipeline stage, but do NOT need to change any other part of this loop. Especially, **be careful not to change the output format of printState**. Within each pipeline stage, the code will compute the new values of the pipeline register data structures (stored in the “new” structure) as a function of the old values (stored in the “state” structure). In other words, **new** should appear on the left-hand-side of your equations, and **state** should appear on the right-hand-side. Then, after the code in all the stages have computed their values, the “memcpy” at the end of the simulator loop copies the values from the **new** structure into the **state** structure. This corresponds to the rising edge of the clock latching values into the pipeline registers for the next clock cycle.

## 5.2 Dealing with Data Hazards

Your simulator should deal with data hazards by bypassing values from the pipeline register data structures. You can implement such data forwarding by checking for data dependences in the execute stage. For every instruction that enters the execute stage, you will have to check against the results produced by the previous 3 instructions (whose results can be found in the EXMEM, MEMWB, and WBEND pipeline registers). If there are no data dependences, then the execute stage should take its operands from the **readRegA** and **readRegB** IDEX pipeline registers. If there are data dependences, then the execute stage should instead copy the results from the pipeline register of the dependent instruction.

Most data hazards can be resolved using bypassing. However, there is one case that requires stalling the pipeline. If an instruction uses a source register that is the destination register of an immediately preceding load instruction, then the pipeline must be stalled for a single cycle. This can be implemented by checking for such a dependence in the decode stage and inserting a bubble (NOP instruction - see Section 5.4.2) instead of allowing the instruction to proceed. One special case is when a load from a location is immediately followed by a store. The depending store can be bypassed by forwarding from the MEM/WB latch (loaded value) to the data memory write port of the memory stage (store instruction). However, for your implementation, you will not need to implement this; simply stall the pipeline one clock cycle for ALL load instructions that are followed by a depending instruction, even if the depending instruction is a store.

## 5.3 Dealing with Control Hazards

The pipeline you will be simulating will have a branch delay of 2 cycles since the branch direction is not resolved until the end of the execute stage. Instead of stalling the pipeline for 2 cycles after every fetched branch, your simulator should implement a “hybrid” static branch prediction scheme. In this scheme, you should predict taken for backward branches, and predict not-taken for forward branches. To implement this hybrid scheme, test the immediate value in the fetch stage on every fetched branch instruction. If the immediate value is positive, then fetch the next consecutive instruction on the following cycle. If the immediate value is negative, then fetch the branch target (computed as a PC-relative address using the offset) on the following cycle.

Make sure that your simulator validates the branch direction computed in the execute stage against the predicted direction. If the prediction was correct, no action should be taken. If the prediction was incorrect, then the simulator must squash the two instructions in the branch delay, which at this point will be in the IFID and IDEX pipeline registers. This squashing can be accomplished by replacing the incorrectly fetched instructions with NOP instructions and clearing all the other state in the IFID and IDEX pipeline registers.

## 5.4 Miscellaneous

### 5.4.1 Memory

As indicated by the **state\_t** structure described in Section 5.1, there are two arrays that implement memory, an instruction memory array **instrMem** and a data memory array **dataMem**. This simulates the separate instruction and memory structures in the pipeline in Figure A.18 of the text. The code we have provided initializes both of these arrays to the same values read in from the assembly code file. In your simulator,

you should read instructions from the `instrMem` array in the fetch stage, and write (read) values to (from) the `dataMem` array in the memory stage.

In the simulator code we have provided for you, the amount of memory simulated is determined by the size of the assembly program file that you read into the simulator. The `numMemory` field of the `state_t` structure is set to this size during initialization and is fixed for the duration of the simulation. This means that you must allocate all the memory your program will need statically in the assembly code file. The maximum size of the assembly program allowed is set by the `MAXMEMORY` constant declared in `mips-small-pipe.h` and is currently 16K words (64K bytes).

#### 5.4.2 NOP Instruction

The MIPS ISA does not include an explicit NOP (null operation) instruction, so neither does our reduced MIPS ISA. However, the NOP instruction is needed to initialize all the instruction fields of the pipeline register data structures, and to replace or “squash” those instructions in the pipeline following a branch misprediction. In your simulator, you will use the “`add 0 0 0`” instruction as a NOP instruction (since this instruction does not effect any state). We have already declared this as `NOPINSTRUCTION` and used it in the initialization code.

#### 5.4.3 Halting

When your simulator encounters the “HALT” instruction, it should end the simulation. Notice, however, that it is incorrect to halt as soon as the HALT instruction is fetched since this code may be speculative (dependent on a yet to be verified branch). If the branch was mispredicted, then you definitely do not want to halt. Another issue is that any ‘sw’ instructions which are farther along the pipeline than the halt must be allowed to complete before the machine is stopped. To solve these problems, halt the machine when the HALT instruction reaches the MEMWB pipeline register. This ensures that all previously executed instructions have completed.

#### 5.4.4 Implementation Dependencies

There are a few implementation dependencies you will need to be aware of to match the reference output. First, if any instruction tries to write R0, instead of just ignoring the write, force the written value (`EXMEM.aluResult` or `MEMWB.writeData`) to 0 and send it through the pipeline like any other instruction. Second, propagate the value of `readRegB` from IDEX to EXMEM, even if it is not needed. Do not perform forwarding unless an instruction actually needs it. In other words, `EXMEM.readRegB` should be set to `IDEX.readRegB` unless the EXecuting instruction needs forwarding. For branches, set `aluResult` to the taken branch address whether or not the branch is actually taken. Lastly, for a HALT instruction, set `aluResult` to 0.

### 5.5 Grading

We will grade your programming assignment based on correct functionality. In other words, for any valid reduced MIPS ISA program, your simulator should accurately simulate the pipeline and produce the correct values for all the pipeline registers at each cycle. We will be using the submit server to validate your simulator, so make sure you test your simulator on several test cases (in other words, you should write several assembly programs to test your simulator). You must use the simulator loop template and the `printState` routine that we have given you in their unmodified form. Each time you call `printState`, it should print in the format that we have provided, and you should only call `printState` once every iteration of the simulator loop (you are free to use `printState` as much as you want when debugging, but take all the extra `printState` calls out of your code before handing in your assignment). Finally, compare the output of your simulator on the `simple.s` program to output given in `simple.output`. There should be no differences (i.e., running `diff simple.output <your output file>` should yield no differences).

## 5.6 Academic Honesty

You may work in pairs on this assignment if you choose; both partners must submit the same code under their own username. Pairs need to be registered with Darth Hugue, in email to [darth.hugue@gmail.com](mailto:darth.hugue@gmail.com) with “cm411 project partners” in the subject. Do not allow any student other than your partner to see any of your code. You may however discuss the assignment in general terms with other students. If copying or excessive collaboration is detected in your submissions, the matter will be referred to the Student Honor Counsel.

## 6 Runtime Environment

You are free to code anywhere you like; Grace accounts have been provided for your convenience. We will run and grade your code on the submit server (<http://submit.cs.umd.edu/summer2011>). It must work correctly there to receive credit.

## 7 Submission

You will submit your `mips-small-pipe.c` and `mips-small-pipe.h` using the submit server. You may either put these files in a zip or tar archive and upload it via the submit server’s web interface (<http://submit.cs.umd.edu/>). Or, you can use new submit server feature to upload both of those files without archiving them. A `.submit` file is included in the `mips-pipe` directory in case you are using Eclipse.

If you choose to work in pairs, and register your pair with Darth Hugue as described above, each partner must submit an identical copy of the source to the submit server under their own username. In other words, if you work with a partner, you are responsible for submitting the code for yourself. If you do not have a submission on the submit server, you will get zero points for this project. Put the names and directory IDs of both partners in a comment at the top of your `mips-small-pipe.c`. Failure to declare your partner may result in your being flagged for academic dishonesty.
