Abstract

The PAC learning of rectangles has been studied because they have been found experimentally to yield excellent hypotheses for several applied learning problems. Also, pseudorandom sets for rectangles have been actively studied recently because (i) they are a subproblem common to the derandomization of depth-2 (DNF) circuits and derandomizing Randomized Logspace, and (ii) they approximate the distribution of \( n \) independent multivalued random variables. We present improved upper bounds for a class of such problems of “approximating” high-dimensional rectangles that arise in PAC learning and pseudorandomness.

**Key words and phrases.** Rectangles, machine learning, PAC learning, derandomization, pseudorandomness, multiple-instance learning, explicit constructions, Ramsey graphs, random graphs, sample complexity, approximations of distributions.
1 Introduction

A basic common theme of a large part of PAC learning and derandomization/computational pseudorandomness is to “approximate” a structure using a “small” number of representative random examples. A commonly studied such type of structure in both learning and derandomization are the \( n \)-dimensional combinatorial rectangles, i.e., sets of the form \( S_1 \times S_2 \times \cdots \times S_n \), where each \( S_i \subseteq \mathbb{R} \); an important special case is where each \( S_i \) is an interval, in which case we have the usual geometric (axis-aligned) rectangles. The PAC learning of rectangles has been studied because they have been found experimentally to yield excellent hypotheses for a variety of applied learning problems (see [38, 12]). Also, pseudorandom sets for rectangles have been actively studied recently [29, 4, 14, 25, 11, 20, 6] because (i) they are a subproblem common to the derandomization of depth-2 (DNF) circuits and derandomizing Randomized Logspace (RL), and (ii) they approximate the distribution of \( n \) independent multivalued random variables. In this work, we present improved (and in some cases optimal) upper bounds for a class of such “approximating rectangles” problems in learning and derandomization.

(a) Learning from multiple-instance examples. We describe and analyze a new algorithm for a practical learning problem, motivated by drug discovery, introduced by Dietterich, Lathrop and Lozano-Perez [12]. Their problem boils down to that of learning an axis-parallel rectangle \( B \) in \( \mathbb{R}^n \) from multi-instance examples. An \( r \)-instance example consists of \( r \) elements of \( \mathbb{R}^n \), together with a label indicating whether any of the instances of this example are in \( B \). The idea is that each multi-instance example represents a molecule and the instances represent different shapes of this molecule. The molecule “works” if at least one of its shapes can bind to some site. This is possible if the measurements of the shape are in the target region \( B \). After receiving a sample of multi-instance examples the learning algorithm is supposed to output a hypothesis \( H \subseteq \mathbb{R}^n \) which is close to the target rectangle \( B \), in the sense that it is likely to correctly classify another \( r \)-instance example as to whether any of its instances are in \( B \).

This problem has previously been studied in Valiant’s PAC framework [36]. In [26], it was proved that if all instances are drawn independently from a product distribution on \( \mathbb{R}^n \), the target rectangle can be learned from \( r \)-instance examples in \( \tilde{O} \left( \frac{n^{5+12}}{\varepsilon^{20}} \right) \) time, where \( \varepsilon \) and \( \delta \) are accuracy and confidence parameters.

In this paper we present a new learning algorithm which does not require that the distribution on \( \mathbb{R}^n \) is a product distribution and which takes only \( \tilde{O} \left( \frac{n^{5+12}}{\varepsilon^{20}} \right) \) time. This algorithm can be modified slightly to achieve similar results in the statistical query model; applying the results of Kearns [21], this implies that it can be made robust against classification noise. Blum and Kalai [8] recently improved on these results.

Our algorithm is substantially different from those previously proposed for this problem [12, 26]. We believe that a variant of our algorithm will prove useful in practice. Initial empirical results [7] support this belief: a straightforward implementation of a variant of our algorithm performs competitively on datasets used in [12].

Our analysis still requires that all instances are drawn independently. We point out that if the \( r \) instances of each example are allowed collectively to be generated according to an arbitrary distribution, the resulting learning problem is much harder. If rectangles could be learned in this model from multi-instance examples then DNF formulas could be learned in the original PAC model, a longstanding open problem. Furthermore, we show that a polynomial-time learning algorithm which outputs a rectangle as its hypothesis only exists if \( \mathcal{NP} = \mathcal{RP} \).
(b) Learning from single-instance examples. We show that the “closure algorithm” [19],
which takes time linear in the size of the sample, PAC learns axis-aligned rectangles in $\mathbb{R}^n$ in the
original (one-instance) PAC model from $O\left(\frac{n \log \frac{1}{\varepsilon}}{\epsilon}\right)$ examples. This matches the lower bound of
[13] to within a constant factor. This is the first example we know of an infinite concept class
used in practice whose PAC learning sample complexity has been determined to within a constant
factor. Our bound improves on the $O\left(\frac{n \log \frac{1}{\varepsilon} + \log \frac{1}{\delta}}{\epsilon}\right)$ bound that follows from the general results
of Blumer, Ehrenfeucht, Haussler and Warmuth [9], and on the bound of $O\left(\frac{n \log \frac{1}{\varepsilon}}{\epsilon}\right)$ that follows
from the general results of Haussler, Littlestone and Warmuth [19].

In our analysis, we bound the $p$-norm of the error of the algorithm’s hypothesis as a function of the
random sample it receives, where $p = \ln(1/\delta)$. A side effect of our analysis is that for all $p$, after
$m$ examples, this norm is at most $\frac{n+p}{m}$. The bound of [19] was obtained by analyzing the expected
error (i.e. the 1-norm).

(c) Pseudorandom sets for combinatorial rectangles. One major goal in derandomization is
to efficiently construct a discrete structure (e.g., constant-degree expanders (Lubotzky, Phillips and
Sarnak[27]), dispersers and extractors (Nisan [31]), hash function families (Carter and Wegman
[10])) that is usually easily shown to exist by a probabilistic argument. Converting randomized
algorithms to deterministic ones is one of the many applications of such results. Another application
is that a random construction (notably of hashing families and error-correcting codes) could require
enormous storage, thus requiring a succinct explicit construction. This area was enriched by the key
observation of Naor and Naor that randomized algorithms are usually robust to approximating
the distribution of $n$ i.i.d. unbiased random bits $X_1, X_2, \ldots, X_n$ [29]. A natural generalization
of this is to allow the $X_i$ to have arbitrary independent distributions on any finite set, and is
formalized as the following problem of pseudorandom sets for combinatorial rectangles. Let $\mathcal{R}^n_m =
\{S_1 \times \cdots \times S_n : \forall i, S_i \subseteq \{0, 1, \ldots, m - 1\}\}$ be a set of $n$-dimensional combinatorial rectangles.
Call a finite multiset $S \subseteq [0, m - 1]^n$ an $\varepsilon$-approximation for $\mathcal{R}^n_m$, if for $X$ sampled uniformly at
random from $S$, we have for all $R = S_1 \times \cdots \times S_n \in \mathcal{R}^n_m$ that $|\Pr(X \in R) - (\prod_i |S_i|)/m^n| \leq \varepsilon$.
That is, w.r.t. events in $\mathcal{R}^n_m$, a random sample from $S$ should look roughly like a random sample
from $[0, m - 1]^n$.

The goal here is to construct a “small” such “pseudorandom” set $S$ deterministically. (There is
a constant $c_0 > 0$ such that a multi-set of $c_0 m n / \varepsilon^2$ points chosen at random from $[0, m - 1]^n$,
forms an $\varepsilon$-approximation with high probability.) To make our goal precise, let us first define the
notion of indexability. Let $S = \{s_1, s_2, \ldots, s_\ell\} \subseteq \{0, 1\}^l$ be any set; let $s_i = (s_{i,1}, s_{i,2}, \ldots, s_{i,l})$, with
$s_{i,j} \in \{0, 1\}$. We say $S$ is indexable if each $s_{i,j}$ can be generated “efficiently” and deterministically:
more precisely, in deterministic $\text{poly}(\log(\ell t))$ time. A major open question is to explicitly construct
an indexable $\varepsilon$-approximation $S$ for $\mathcal{R}^n_m$, such that $\log |S| = O(\log m + \log n + \log(1/\varepsilon))$.
Progress on this has been made very recently in Armoni, Saks, Wigderson & Zhou [6], constructing an
indexable $S$ with $\log |S| = O(\log m + \log n + \log^2(1/\varepsilon))$. Hence, the key problem is to improve
the $O(\log^2(1/\varepsilon))$ term, to the eventual target of $O(\log(1/\varepsilon))$. Why would this be a significant
improvement? Recall that derandomized algorithms based on such constructions first explicitly
construct the set $S$, and then try out each element of $S$ in succession, as their “random” seed. Thus,
such an improvement will very much reduce the running times of the corresponding derandomized
algorithms: $\text{poly}((1/\varepsilon)^{\log(1/\varepsilon)})$ will become $\text{poly}(1/\varepsilon)$.

Another related direction for progress is as follows. Given $R = S_1 \times S_2 \times \cdots \times S_n \in \mathcal{R}^n_m$, we shall say
R is trivial in dimension i iff $S_i = \{0, 1, \ldots, m-1\}$; R is nontrivial in dimension i otherwise. Given any integer $k \leq n$, let $\mathcal{R}_{m,k}$ contain the elements of $\mathcal{R}_{n,k}$ that are nontrivial in at most $k$ dimensions. In analogy with k-wise and almost k-wise independence ([28, 3, 29, 4]), it is also an important open question to construct a good $\epsilon$-approximation $S_0$ for $\mathcal{R}_{m,k}$ (note that $\mathcal{R}_{n,k} = \mathcal{R}_{n,m,n}$). The major goal here is to achieve an indexable $S_0$ with $\log |S_0| = O(\log \log n + \log k + \log m + \log(1/\epsilon))$. This would be optimal to within a constant factor, and by setting $k = n$, we would also get the required construction for $\mathcal{R}_{n,n}$.

We first show how to convert the construction of [6] to get an indexable $\epsilon$-approximation $S$ for $\mathcal{R}_{m,k}$ with $\log |S| = O(\log \log n + \log m) log(1/\epsilon)$ and $\epsilon = m^{-c_2}$ for certain absolute constants $c_1, c_2 > 0$, i.e., if $\epsilon$ is sufficiently small. Often, $\epsilon$ is in fact as small as $\exp(-\Theta(k))$, e.g., in many applications of almost k-wise independent random bits. Thus, the main determining factor for comparing the construction of [6] with ours seems to be whether $\epsilon = m^{-c_2}$ or not. If $\epsilon$ is “small”, e.g., if $m$ is $O(\text{polylog}(1/\epsilon))$, then we get good improvements.

Of equal interest is the fact that our approach suggests a potential way of improving on it: see Theorem 18 for a bootstrapping approach.

(d) Pseudorandom sets for axis-aligned rectangles, and constructions of Ramsey-type graphs. Call an undirected graph $G$ an $(s,t,n)$-graph iff it has $n$ vertices, has clique number $\omega(G) \leq s$, and independence number $\alpha(G) \leq t$. One of the first applications of the probabilistic method was the proof by Erdős that $(2\log_2 n, 2\log_2 n, n)$-graphs (also known as Ramsey graphs since they provide lower bounds for the graph Ramsey function) exist [15]. It is still an outstanding open question to explicitly construct such graphs; the current-best are the breakthroughs of Frankl and Wilson, who constructed $(2^{O(\sqrt{\log n \log \log n})}, 2^{O(\sqrt{\log n \log \log n})}, n)$-graphs [17, 18]. Similarly, while nonconstructive progress has been made on the (“off-diagonal” or “Ramsey-type”) case of $s \neq t$ [5], where we assume w.l.o.g. that $s < t$, very few constructive results are known; see, e.g., [2] for a construction of $(2, O(n^{2/3}), n)$-graphs. (It is known that $(2, \Theta(\sqrt{n \log n}), n)$-graphs exist.)

We present a family of improved deterministic sequential and parallel (EREW PRAM) constructions for Ramsey-type graphs here, using $\epsilon$-approximations for axis-aligned rectangles in $\{0,1,\ldots,m-1\}^n$. For instance, we show parallel constructions of, e.g., $(2^{O(\sqrt{\log n})}, 2^{O(\sqrt{\log n})}, n)$-graphs using $n^{O((\log \log n)^2)}$ processors and polylog$(n)$ time. (If we are willing to expend $n^{O(\log n)}$ processors, it is known that we can use “almost $2^{O(\log^2 n)}$-wise independent random bits” [29] to construct $(2\log_2 n, 2\log_2 n, n)$-graphs in polylog$(n)$ time.) At the other end of the spectrum, we show, e.g., that for arbitrarily small constants $\alpha, \beta > 0$, we can construct $(c, n^\alpha, n)$-graphs using $\exp(n^\beta)$ processors and $O(n^\alpha)$ time, where $c = c(\alpha, \beta)$ is a constant. (Direct application of previous techniques such as “almost $n^{\Theta(1)}$-wise independent random variables” will have the processor complexity necessarily of the form $\exp(n^{f(n)})$ for some function $f$, and not $\exp(n^\beta)$ for an arbitrarily small constant $\beta > 0$, as we have here.) To our knowledge, even the sequential counterparts of these parallel algorithms have not been presented before.

Section 2 sets up some preliminary definitions. We then show the learning theory results in Sections 3 and 4. The derandomization and Ramsey graph constructions are presented in Sections 5 and 6. The appendix shows some technical proofs.
2 Definitions

Denote the reals by $\mathbb{R}$ and the positive integers by $\mathbb{N}$. We sometimes abbreviate “random variable” as “r.v.” We use the unit cost RAM model of computation.

For each $n \in \mathbb{N}$, for each $\overline{a}, \overline{b} \in \mathbb{R}^n$, let $B_{\overline{a}, \overline{b}} = \prod_{i=1}^{n}[a_i, b_i]$, and let $B_{\overline{b}} = \prod_{i=1}^{n}(-\infty, b_i]$. Define $\text{BOXES}_n = \{B_{\overline{a}, \overline{b}} : \overline{a}, \overline{b} \in \mathbb{R}^n\}$, $\text{BOXES}_{n,m} = \{B \cap \{0, \ldots, m-1\}^n : B \in \text{BOXES}_n\}$, and $\text{OBOXES}_n = \{B_{\overline{b}} : \overline{b} \in \mathbb{R}^n\}$. Finally, a class of combinatorial rectangles that we work with:

$$\mathcal{R}_{m}^n = \{\prod_{i=1}^{n} X_i : X_1, \ldots, X_n \subseteq \{0, \ldots, m-1\}\}.$$

3 Learning from multiple-instance examples

First we give a formal description of the learning problem.

Let $n, r \in \mathbb{N}$. A tuple $((\overline{x}_1, \ldots, \overline{x}_r), y)$ with each $\overline{x}_i \in \mathbb{R}^n$ and with $y \in \{0, 1\}$ is called an $r$-instance example. A sample is a sequence of $r$-instance examples. For a finite sequence $\sigma = ((\overline{x}_{s,i})_{i=1}^{r})_{s=1}^{t}$ of instances and a rectangle $B$, the sample generated by $\sigma$ and $B$ is

$$S_{B, \sigma} = ((\overline{x}_{1,1}, \ldots, \overline{x}_{1,r}), y_1), \ldots, ((\overline{x}_{t,1}, \ldots, \overline{x}_{t,r}), y_t),$$

where

$$y_s = \psi_B(\overline{x}_{s,1}, \ldots, \overline{x}_{s,r}) = \begin{cases} 1 & \text{if } \exists i \in \{1, \ldots, r\} : x_{s,i} \in B \\ 0 & \text{if } \forall i \in \{1, \ldots, r\} : x_{s,i} \notin B \end{cases}$$

for $s = 1, \ldots, t$.

A learning algorithm receives a sample $S$ and an accuracy parameter $\epsilon$ and outputs a hypothesis $H(S, \epsilon) \subseteq \mathbb{R}^n$. The error of a hypothesis $H$ in respect to a probability distribution $D$ on $\mathbb{R}^n$ is measured by the probability that a random $r$-instance is misclassified, i.e. by $\text{er}_{B,D}(H) = D^r((\overline{x}_1, \ldots, \overline{x}_r) : \psi_B(\overline{x}_1, \ldots, \overline{x}_r) \neq \psi_H(\overline{x}_1, \ldots, \overline{x}_r))$. Here and elsewhere $D^r$ denotes the distribution obtained by sampling $r$ times independently from $D$.

Definition 1 A learning algorithm learns $\text{BOXES}_n$ from $r$-instance examples with sample complexity $\ell(n, r, \epsilon, \delta)$ if the learning algorithm calculates a hypothesis $H(S, \epsilon)$ such that for all $B \in \text{BOXES}_n$, for all distributions $D$ on $\mathbb{R}^n$, for all $\epsilon, \delta > 0$, for all $\ell \geq \ell(n, r, \epsilon, \delta)$

$$D^r \{\sigma : \text{er}_{B,D}(H(S_{B,\sigma}, \epsilon)) \geq \epsilon\} < \delta.$$

The following is the main result of this section.

Theorem 2 There is a learning algorithm that learns $\text{BOXES}_n$ from $r$-instance examples with sample complexity $\ell = O\left(\frac{n^2r^2}{\epsilon^2} \log \frac{\log n}{\delta}\right)$. The run-time of the algorithm is $O(n \ell \log \ell)$.
3.1 The algorithm

First, observe that $a_k \leq x_k \leq b_k \iff -x_k \leq -a_k \land x_k \leq b_k$. Thus BOXES$_n$ can be learned if BOXES$_{2n}$ can be learned (see [33]). (A similar trick was employed in [22, 24].) We therefore give an algorithm for learning BOXES$_n$ for each $n$.

The algorithm for learning BOXES$_n$ learns the faces $b_1, \ldots, b_n$ of the target $B = \prod_{k=1}^{n} (-\infty, b_k]$ independently. It tries to calculate an estimate $\hat{b}_k \leq b_k$ such that $D\{(x_1, \ldots, x_n) : (x_1, \ldots, x_n) \in B \land x_k > \hat{b}_k\}$ is small. If this can be done for all $k$ then the hypothesis $\prod_{k=1}^{n} (-\infty, \hat{b}_k]$ is contained in the target rectangle and its error is small. Now the main observation is that, despite the fact that examples do not indicate whether individual instances lie in $B$, we can still estimate $\beta_k(b) = D\{(x_1, \ldots, x_n) : (x_1, \ldots, x_n) \in B \land x_k > b\}$ from the sample. Thus the algorithm just has to pick a $\hat{b}_k$ such that the estimate $\hat{\beta}_k(b)$ is small while still guaranteeing that $\hat{b}_k \leq b_k$.

Let $q = [1 - D(B)]^r$ (note that this is just the probability that an $r$-instance example is labelled 0) and $\alpha_k(b) = D\{(x_1, \ldots, x_n) : x_k > b\}$. See Figure 1. If we define $\varphi_k(b) = D^r\{(\bar{x}_1, \ldots, \bar{x}_r) : \psi_B(\bar{x}_1, \ldots, \bar{x}_r) = 0 \land x_{1,k} > b\}$, then

$$\varphi_k(b) = [\alpha_k(b) - \beta_k(b)] \cdot [1 - D(B)]^{r-1} = [\alpha_k(b) - \beta_k(b)] \cdot q^{1-1/r}. \quad (1)$$

Since $q$, $\alpha_k$, and $\varphi_k$ can be estimated from a sample $S$, we get an estimate for $\beta_k$ by solving (1) for $\beta_k$: we set $\hat{q} := \{1 \leq s \leq \ell : y_k = 0\}/\ell$, $\hat{\alpha}_k(b) := \{1 \leq s \leq \ell : x_{s,1,k} > b\}/\ell$, $\hat{\varphi}_k(b) := \{1 \leq s \leq \ell : x_{s,1,k} > b \land y_k = 0\}/\ell$, and $\hat{\beta}_k(b) := \hat{\alpha}_k(b) - \frac{\hat{\varphi}_k(b)}{\hat{q}^{1-1/r}}$. Finally, observe that $\text{er}_{B,D}(R^n) < \epsilon$ if $\hat{q} < \epsilon$ and $\text{er}_{B,D}(\emptyset) < \epsilon$ if $\hat{q} > 1 - \epsilon$. We get the following algorithm.

Input: a sample $S$ of size $\ell$ and an accuracy parameter $\epsilon$.

If $\hat{q} < \epsilon/2$ then return $R^n$ and halt, and if $\hat{q} > 1 - \epsilon/2$ then return $\emptyset$ and halt.

For $k = 1, \ldots, n$ do

$$\hat{b}_k := \min \{x_{s,1,k} : 1 \leq s \leq \ell \land \hat{\beta}_k(x_{s,1,k}) \leq \frac{\epsilon}{16nrq^{1-1/r}}\}.$$ 

Return $B(\hat{b}_1, \ldots, \hat{b}_n)$.

For each $k$ the $\hat{\beta}_k(x_{s,1,k})$ can be calculated incrementally after sorting the $x_{s,1,k}$. Thus the run-time of the algorithm is $O(n\ell \log \ell)$.

3.2 Analysis of the algorithm

It remains to show that the estimate $\hat{b}_k$ is sufficiently accurate that the error of the hypothesis of the algorithm is small enough.

The next lemma gives a sufficient condition on the accuracy of the estimates $\hat{q}$, $\hat{\alpha}_k$, and $\hat{\varphi}_k$. Theorem 2 is then proved by applying uniform convergence bounds.

Lemma 3 Let $0 < \epsilon < 1/2$ and let $H$ be the hypothesis of the algorithm based on a sample $S_{B,\sigma}$. If for all $k \in \{1, \ldots, n\}$ and all $b \in R$

$$\max \{|q - \hat{q}|, |\alpha_k(b) - \hat{\alpha}_k(b)|, |\varphi_k(b) - \hat{\varphi}_k(b)|\} \leq \frac{\epsilon}{256nr},$$

then $\text{er}_{B,D}(H) < \epsilon$. 

8
**Proof:** We claim that for the non-trivial case \( \frac{\epsilon}{2} \leq \hat{q} \leq 1 - \frac{\epsilon}{2} \), the following inequalities

\[
\frac{\epsilon}{4} \leq q \leq 1 - \frac{\epsilon}{4},
\]

\[
q^{1-1/r}/2 \leq \hat{q}^{1-1/r} \leq 2q^{1-1/r},
\]

\[
|\beta_k(b) - \hat{\beta}_k(b)| \leq \frac{\epsilon}{32nrq^{1-1/r}}
\]

hold for all \( k \) and \( b \). Inequalities (3) and (4) are obvious; we now prove (5).

It is easy to show using calculus that for all \( x, y > 0 \)

\[
|x^{1-1/r} - y^{1-1/r}| \leq |x - y| \left( \frac{1}{\min\{x, y\}} \right)^{1/r}.
\]

Fix \( k \) and \( b \) (and drop them from the subscripts of all variables). Expanding the definition of \( \hat{\beta} \) and applying (1), we have

\[
|\beta - \hat{\beta}| = \left| \left( \alpha - \frac{\varphi}{q^{1-1/r}} \right) - \left( \hat{\alpha} - \frac{\hat{\varphi}}{\hat{q}^{1-1/r}} \right) \right|.
\]

Bounding \( |\alpha - \hat{\alpha}| \) using (2) and simplifying the rest, we get

\[
|\beta - \hat{\beta}| \leq \frac{\epsilon}{256rn} + \frac{\epsilon}{256rn} + \frac{2|\varphi q^{1-1/r} - \hat{\varphi} q^{1-1/r}|}{q^{2-2/r}}.
\]

Applying (4), we get

\[
|\beta - \hat{\beta}| \leq \frac{\epsilon}{256rn} + \frac{2|\varphi q^{1-1/r} - \hat{\varphi} q^{1-1/r}|}{q^{2-2/r}}.
\]

Applying (2) and the fact that \( \varphi \leq q \), we have

\[
|\beta - \hat{\beta}| \leq \frac{\epsilon}{256rn} + \frac{\epsilon}{128rnq^{1-1/r}} + \frac{2|q^{1-1/r} - q^{1-1/r}|}{q^{2-2/r}}.
\]

Applying (6), we get

\[
|\beta - \hat{\beta}| \leq \frac{\epsilon}{256rn} + \frac{\epsilon}{128rnq^{1-1/r}} + \frac{2q - q^{1-1/r}}{(\min\{q, \hat{q}\})^{1/r} q^{2-2/r}}.
\]

By (2), \( \hat{q} \geq q - \epsilon/(256nr) \), so by (3), \( \hat{q} \geq q - q/(64nr) \geq q/2 \). Therefore, (7) implies

\[
|\beta - \hat{\beta}| \leq \frac{\epsilon}{256rn} + \frac{\epsilon}{128rnq^{1-1/r}} + \frac{4q - q^{1-1/r}}{q^{1-1/r}}.
\]

Applying (2) yields (5).
We claim that \( \hat{b}_k \leq b_k \) and that
\[
\beta_k(\hat{b}_k) \leq \frac{\epsilon}{4nrq^{1-1/r}}. \tag{8}
\]
Observe that if \( x_{s,1,k} > b_k \) for all \( s \in \{1, \ldots, \ell \} \) then \( \hat{\alpha}_k(b_k) = 1 \) whereas \( \alpha_k(b_k) \leq 1 - D(B) = q^{1/r} \leq (1 - \epsilon/4)^{1/r} \leq 1 - \frac{\epsilon}{8r} \) by (3) which contradicts (2). Hence there are some \( x_{s,1,k} \leq b_k \). Let
\[
c_k = \max\{x_{s,1,k} : 1 \leq s \leq \ell, x_{s,1,k} \leq b_k \}.
\]
Then \( \beta_k(c_k) = \beta_k(b_k) \leq \frac{\epsilon}{32nrq^{1-1/r}} \leq \frac{\epsilon}{16nrq^{1-1/r}} \) by (5) and (4) since \( \beta_k(b_k) = 0 \). Thus \( \hat{b}_k \leq b_k \). Furthermore,
\[
\beta_k(\hat{b}_k) \leq \beta_k(b_k) + \frac{\epsilon}{32nrq^{1-1/r}} \leq \frac{\epsilon}{16nrq^{1-1/r}} + \frac{\epsilon}{32nrq^{1-1/r}} \leq \frac{\epsilon}{8nrq^{1-1/r}} + \frac{\epsilon}{32nrq^{1-1/r}} \leq \frac{\epsilon}{4nrq^{1-1/r}},
\]
again by (5) and (4) and the choice of \( \hat{b}_k \) in the algorithm.

Finally an \( r \)-instance is misclassified by \( H = \prod_{k=1}^{n} (-\infty, \hat{b}_k] \) only if no instance is in \( H \) and at least one instance is in \( B \), i.e. at least one coordinate of this instance is in \( (\hat{b}_k, b_k] \) for the corresponding \( k \). The probability of drawing such an instance is at most \( \beta_k(b_k) - \beta_k(\hat{b}_k) = \beta_k(\hat{b}_k) \). To bound the probability that a random instance is not in \( H \) we find
\[
1 - D(H) \leq 1 - D(B) + \sum_{k=1}^{n} \beta_k(\hat{b}_k)
\]
\[
\leq q^{1/r} + \frac{\epsilon}{4nrq^{1-1/r}} \leq q^{1/r} (1 + 1/r)
\]
by (8) and (3). Hence
\[
er_{B,D}(H) \leq \sum_{k=1}^{n} \beta_k(\hat{b}_k) \cdot \left[ 1 - D(H) \right]^{r-1}
\]
\[
\leq nr \cdot \frac{\epsilon}{4nrq^{1-1/r}} \cdot [q^{1/r}(1 + 1/r)]^{r-1}
\]
\[
\leq \epsilon
\]
by (8).

Now we turn to analyzing the number of examples required to ensure (2). This analysis uses standard techniques, but we include it in an appendix for completeness.

**Lemma 4** There is a constant \( c \) such that for all \( 0 < \epsilon, \delta < 1/2 \), if \( l \geq \frac{cn^2r^2}{\epsilon^2} \log \frac{n}{\delta} \), then
\[
\Pr(|q - \hat{q}| > \frac{\epsilon}{256nr}) \leq \frac{\delta}{n + 1}, \tag{9}
\]
and for each \( k \in \{1, \ldots, n\} \),
\[
\Pr(\exists b, \max\{|\alpha_k(b) - \hat{\alpha}_k(b)|, |\varphi_k(b) - \hat{\varphi}_k(b)|| > \frac{\epsilon}{256nr}) \leq \frac{\delta}{n + 1}. \tag{10}
\]
Proof: In Appendix A.

Proof of Theorem 2: Combine Lemmas 3 and 4.

3.3 The hardness of learning from dependent multiple-instance examples

Definition 5 A learning algorithm learns BOXES_n from dependent r-instance examples if the learning algorithm calculates a hypothesis \( H(S,e) \) such that for all \( B \in \text{BOXES}_n \), for all distributions \( D \) on \((\mathbb{R}^n)'\), for all \( \epsilon, \delta > 0 \), for all \( \ell \geq \ell(n,r,\epsilon,\delta) \), \( D^\ell(\sigma : e_{r,B,D}(H(B,S_\sigma,e)) \geq \epsilon) < \delta \).

Theorem 6 If there is a \( \text{poly}(n,r,1/\epsilon,1/\delta) \)-time algorithm \( A \) for learning BOXES_n from dependent r-instance examples, then there is a \( \text{poly}(n,r,1/\epsilon,1/\delta) \)-time algorithm \( A' \) for learning r-term DNF formulas over \( n \) variables (from 1-instance examples).

If \( A \) in addition outputs axis-aligned rectangles as its hypotheses then \( \mathcal{RP} = \mathcal{NP} \).

Proof: We reduce learning an r-term DNF \( f = C_1 \lor \ldots \lor C_r \) over \( n \) variables \( x_1, \ldots, x_n \) to learning a rectangle in \( \mathbb{R}^n \) from r-instance examples. For each truth setting \( \vec{\sigma} \in \{0,1\}^n \), let \( \varphi(\vec{\sigma}) \) be the \( r \) instances \( (v_1, \ldots, v_r, 1/2, \ldots, 1/2), \ldots, (1/2, \ldots, 1/2, v_1, \ldots, v_n) \in \{0,1/2,1\}^n \). We associate \( f \) with \( B_{\vec{a},\vec{b}} \) where for each \( 0 \leq i < r, 1 \leq j \leq n \),

\[
\begin{align*}
a_{i,j} &= 1/2 \text{ and } b_{i,j} = 1 \quad \text{if } x_j \in C_{i+1} \\
a_{i,j} &= 0 \text{ and } b_{i,j} = 1/2 \quad \text{if } \bar{x}_j \in C_{i+1} \\
a_{i,j} &= 0, b_{i,j} = 1 \quad \text{otherwise.}
\end{align*}
\]

Then \( \varphi(\vec{\sigma}) \) is classified by \( B_{\vec{a},\vec{b}} \) iff \( \vec{\sigma} \) satisfies \( f \).

Suppose there is a polynomial \( p \) such that for each \( N, r, \epsilon > 0 \) and \( \delta > 0 \), \( A \) learns BOXES_N from dependent r-instance examples in \( p(N,r,1/\epsilon,1/\delta) \) time. Consider the DNF learning algorithm \( A' \) that, for each example \( (\vec{\sigma}, y) \), gives \( (\varphi(\vec{\sigma}), y) \) to \( A \), and, given the hypothesis \( H_A \subseteq \mathbb{R}^N \), \( N = nr \), output by \( A \), constructs \( H_{A'} \) by letting \( \vec{\sigma} \in H_{A'} \iff \varphi(\vec{\sigma}) \in H_A \). It is easily verified (see [33]), that \( A' \) learns r-term DNF formulas over \( n \) variables in \( \text{poly}(n,r,1/\epsilon,1/\delta) \) time.

Next, we claim that if \( H_A \) labels collections of \( r \) instances according to an axis-aligned hyperrectangle, then \( H_{A'} \) can be expressed as an r-term DNF. Applying the result of Pitt and Valiant [32], that r-term DNF are not learnable using r-term DNF as hypotheses in polynomial time unless \( \mathcal{RP} = \mathcal{NP} \), will complete the proof of the second statement.

Suppose \( H_A = \psi_{B(a_1, \ldots, a_n), (b_1, \ldots, b_n)} \).

- If there exist distinct \( i, i' \in \{0, \ldots, r - 1\} \) such that there are \( j, j' \in \{1, \ldots, n\} \) with \( 1/2 \notin [a_{i,j}, b_{i,j}] \) and \( 1/2 \notin [a_{i',j}, b_{i',j}] \), then the definition of \( \varphi \) implies that \( H_{A'} = \emptyset \), trivially expressed as an r-term DNF.

- If there is a single \( i \in \{0, \ldots, r - 1\} \) such that there exists \( j \) with \( 1/2 \notin [a_{i,j}, b_{i,j}] \), then \( H_{A'} \) can be expressed by the single term \( \hat{C} \), where \( x_j \in \hat{C} \iff 0 \notin [a_{i,j}, b_{i,j}] \) and \( \bar{x}_j \in \hat{C} \iff 1 \notin [a_{i,j}, b_{i,j}] \).

- Otherwise, it is easily verified that \( H_{A'} \) can be expressed as the r-term DNF \( \hat{C}_1 \lor \ldots \lor \hat{C}_r \) obtained by including \( x_j \) in \( \hat{C}_{i+1} \) iff \( 0 \notin [a_{i,j}, b_{i,j}] \) and including \( \bar{x}_j \) in \( \hat{C}_{i+1} \) iff \( 1 \notin [a_{i,j}, b_{i,j}] \).
4 Learning from single-instance examples

Valiant’s PAC model can be obtained from the model described in Section 3 by fixing the number \( r \) of instances to be 1. The following is our main result about this model.

**Theorem 7** There is a learning algorithm \( A \) such that, for all \( \epsilon, \delta > 0, n \in \mathbb{N} \), Algorithm \( A \) \((\epsilon, \delta)\)-learns \( \text{BOXES}_n \) from \( \frac{\epsilon(2n + \lfloor \frac{n}{\delta} \rfloor)}{\epsilon} \) examples in \( O\left(\frac{n(n + \ln \frac{1}{\delta})}{\epsilon}\right) \) time.

As discussed in Section 3, it is sufficient to consider \( \text{OBOXES}_n \). Consider the algorithm \( A \) that, given a sample \( ((\bar{x}_1, y_1), \ldots, (\bar{x}_t, y_t)) \), sets each \( b_k = \max\{x_{i,k} : y_i = 1\} \) and outputs \( H = B(b_1, \ldots, b_n) \). This algorithm is known as the “closure algorithm”, because it outputs the unique smallest element of \( \text{OBOXES}_n \) consistent with the sample.

We begin by characterizing the \( p \)th moment of the error of \( A \)’s hypothesis. For some sequence \( \sigma = \bar{x}_1, \ldots, \bar{x}_t \), define \( \text{er}_{A,B,D}(\sigma) \) to be the error of \( A \)’s hypothesis \( H \) when given \( S_{B,\sigma} \), i.e. \( \text{er}_{B,D}(H(S_{B,\sigma}), \epsilon) \).

**Lemma 8** Choose \( n, \ell, p \in \mathbb{N} \), \( B \in \text{OBOXES}_n \) and a probability distribution \( D \) over \( \mathbb{R}^n \). Then

\[
\mathbb{E}_{\sigma \in D^\ell}(\text{er}_{A,B,D}(\sigma))^p
\]

is equal to the probability, if

- we draw \( \bar{x}_1, \ldots, \bar{x}_{\ell+p} \) independently at random according to \( D \),
- give \( S_{B,(\bar{x}_1, \ldots, \bar{x}_\ell)} \) to \( A \) (only the first \( \ell \) draws are used here), and
- call \( A \)’s resulting hypothesis \( H \),

that \( H \) is incorrect about each of \( \bar{x}_{\ell+1}, \ldots, \bar{x}_{\ell+p} \). That is, that

\[
\{ \bar{x}_{\ell+1}, \ldots, \bar{x}_{\ell+p} \} \subseteq H \Delta B,
\]

where \( \Delta \) denotes the symmetric difference.

**Proof:** For each \( \sigma \in (\mathbb{R}^n)^\ell \), define \( H_\sigma = H(S_{B,\sigma}) \). Expanding the definition yields

\[
\mathbb{E}_{\sigma \in D^\ell}(\text{er}_{A,B,D}(\sigma))^p = \int (\Pr_{\bar{z} \in D}(\bar{z} \in H_\sigma \Delta B))^p dD^\ell(\sigma).
\]

Changing the names of the variables in the \( p \) factors of \( (\Pr_{\bar{z} \in D}(\bar{z} \in H_\sigma \Delta B))^p \) from \( \bar{z} \) to \( \bar{x}_{\ell+1}, \ldots, \bar{x}_{\ell+p} \) respectively, we get

\[
\mathbb{E}_{\sigma \in D^\ell}(\text{er}_{A,B,D}(\sigma))^p = \prod_{i=1}^{p} \Pr_{\bar{x}_{\ell+i} \in D}(\bar{x}_{\ell+i} \in H_\sigma \Delta B) dD^\ell(\sigma)
\]

12
which immediately implies

$$E_{\sigma \in D^l((er_{A,B,D}(\sigma))^p)} = \prod_{i=1}^{p} \Pr_{\vec{x}_{t+1}, \ldots, \vec{x}_{t+p} \in D^p}(\vec{x}_{t+i} \in H_\sigma \Delta B) \ dD^l(\sigma).$$

Applying the definition of independence, we get

$$E_{\sigma \in D^l((er_{A,B,D}(\sigma))^p)} = \prod_{i=1}^{p} \Pr_{\vec{x}_{t+1}, \ldots, \vec{x}_{t+p} \in D^p}(\bigwedge_{i=1}^{p} \vec{x}_{t+i} \in H_\sigma \Delta B) \ dD^l(\sigma). \quad (11)$$

Define $\varphi : (\mathbb{R}^n)^{\ell+p} \to \{0,1\}$ by

$$\varphi(\vec{x}_1, \ldots, \vec{x}_{\ell+p}) = \begin{cases} 1 & \text{if } \bigwedge_{i=1}^{p} \vec{x}_{t+i} \in H(\vec{x}_1, \ldots, \vec{x}_t) \Delta B \\ 0 & \text{otherwise.} \end{cases}$$

Then rewriting (11), we get

$$E_{\sigma \in D^l((er_{A,B,D}(\sigma))^p)} = \int \int \varphi(\vec{x}_1, \ldots, \vec{x}_{\ell+p}) \ dD^p(\vec{x}_{t+1}, \ldots, \vec{x}_{t+p}) \ dD^l(\vec{x}_1, \ldots, \vec{x}_t).$$

Applying Fubini’s Theorem (see [16, volume 2, page 120]) completes the proof. □

The proof of Lemma 8 did not use anything specific about $A$ or OBOXES$_n$; therefore, the lemma can trivially be generalized to any algorithm and concept class.

Next, we record a well-known lemma whose application is commonly known as the “permutation trick”.

**Lemma 9 (see [19])** Choose a set $X$, $m \in \mathbb{N}$, a distribution $D$ on $X$, and a random variable $\varphi$ defined on $X^m$. Let $U$ be the uniform distribution on the permutations of $\{1, \ldots, m\}$. Then

$$\int \varphi(x)D^m(x) \leq \sup_{(x_1, \ldots, x_m) \in X^m} \int \varphi(x_{\sigma(1)}, \ldots, x_{\sigma(m)})U(\sigma).$$

Now we are ready to bound the $p$th moment of the error.

**Lemma 10** Choose $n, p, \ell \in \mathbb{N}$. For Algorithm $A$ (the Closure Algorithm), for any $B \in$ OBOXES$_n$, and for any probability distribution $D$ over $\mathbb{R}^n$, $E_{\sigma \in D^l((er_{A,B,D}(\sigma))^p)} \leq \frac{(\ell + p - 1)}{p^p}.$

**Proof:** Lemma 8 implies that $E_{\sigma \in D^l((er_{A,B,D}(\sigma))^p)}$ is equal to the probability, if (a) we draw $\vec{x}_1, \ldots, \vec{x}_{\ell+p}$ independently at random from $D$ (b) give $S_{B,(\vec{x}_1, \ldots, \vec{x}_\ell)}$ to $A$ (only the first $\ell$ draws are used here), and (c) call the resulting hypothesis $H$, that each of $\vec{x}_{t+1}, \ldots, \vec{x}_{t+p}$ fall in the symmetric difference of $H$ and $B$.

Applying Lemma 9, the above probability is at most the supremum, over $\vec{x}_1, \ldots, \vec{x}_{\ell+p}$, of the probability of the same event with respect to a random permutation of this particular sequence. Since the hypothesis $H$ does not depend on the relative order of the first $\ell$ elements, and the “test” does not depend on the order of the last $p$ elements, we can instead evaluate the probability of the same event with respect to a random choice of which $p$ elements occur last.

Let us call a set of $p$ elements, which, if occurring last, all fall in $B \Delta H$, a “bad set”. We claim that there is a partial mapping $\psi$ from the set of sequences of $n$ nonnegative integers summing to
onto the set of bad sets. The fact that there are known to be only \(\binom{n+p-1}{p}\) such sequences will then complete the proof.

Since the Closure Algorithm outputs the unique smallest hypothesis (call it \(\prod_k(-\infty, \hat{b}_k]\)) containing the examples given to it that are in \(B\), each element \(\vec{x}\) of a bad set must be in \(B - \prod_k(-\infty, \hat{b}_k]\). For convenience, we “blame” \(\vec{x}\)'s misclassification on the least \(k\) such that \(x_k > \hat{b}_k\).

Define a partial map \(\psi\) from the set of sequences \(\vec{t}\) of \(n\) nonnegative integers summing to \(p\) to subsets of \(\{1, \ldots, \ell + p\}\) by the following procedure.

\[
T := \{t : \vec{x}_t \in B\};
U := \emptyset;
\]
for \(k \coloneqq 1\) to \(n\) do

\[
\text{move the } i_k \text{ elements } t \text{ of } T \text{ with the largest values of } x_{t,k} \text{ from } T \text{ to } U;
\]
output \(U\);

If for any time \(k\) through the loop there is a tie for the \(i_k\)th largest element of \(T\), then \(\psi(\vec{t})\) is undefined.

Choose a bad subset \(S\). Let \(\prod(-\infty, \hat{b}_k]\) be the hypothesis output by the closure algorithm when given the sample generated from the instances with indices not in \(S\). For each \(k \in \{1, \ldots, n\}\), define \(C_k\) to be the those elements of \(S\) whose misclassification was blamed on dimension \(k\). We claim that \(S = \psi([C_1], \ldots, |C_n|]\).

Imagine a run of the procedure defining \(\psi\) with its input \(\vec{t}\) set to \((|C_1|, \ldots, |C_n|]\). For each \(k \in \{1, \ldots, n\}\), let \(T_k\) be the value of \(T\) before the \(k\)th time through the loop. Define \(U_k\) similarly for \(U\).

We wish to show that, each time through the loop, the elements of \(C_k\) are moved from \(T\) to \(U\). We prove this by induction by proving the nominally stronger statement that for all \(k\), \(U_k = \cup_{j<k} C_j\). The base case is trivial. Assume the IH holds before some time \(k\) through the loop. Since \(C_1, \ldots, C_n\) are disjoint, the inductive hypothesis implies that none of the elements of \(C_k\) have been moved from \(T\) to \(U\) before the \(k\)th time through the loop.

We claim that the elements of \(C_k\) are the elements of \(T_k\) with the largest \(k\)th components. Assume without loss of generality that \(C_k \neq \emptyset\) and \(C_k \neq T_k\). Choose \(s \in C_k, t \in T_k - C_k\).

- If \(t \notin S\), then \(\vec{x}_t\) was one of the elements of \(B\) given to the closure algorithm, and therefore, \(x_{t,k} \leq \hat{b}_k\).

- Suppose \(t \in S\). By the inductive hypothesis, \(t\) was not blamed on an index less than \(k\), since otherwise it would have been moved to \(U\) before the \(k\)th time through the loop. Therefore, \(t\) must be blamed on an index greater than \(k\). Thus \(x_{t,k} \leq \hat{b}_k\).

So in either case, \(x_{t,k} \leq \hat{b}_k\). But the fact that index \(k\) was blamed for the misclassification of \(\vec{x}_s\) implies that \(x_{s,k} > \hat{b}_k\), and therefore, that \(x_{t,k} < x_{s,k}\). Since \(s\) and \(t\) were chosen arbitrarily, the elements of \(C_k\) are the elements \(t\) of \(T_k\) with the largest values of \(x_{t,k}\) Thus, they are the elements moved from \(T\) to \(U\) during the \(k\)th time through the loop, completing the proof of the inductive step. This implies that the output of the algorithm is \(\cup_{k=1}^n C_k = S\). Since \(S\) was chosen arbitrarily, this implies that \(\psi\) is onto. As described above, this completes the proof.
Proof of Theorem 7: Applying Markov’s inequality together with Lemma 10 implies that
\[
\Pr_{\kappa \in \mathcal{D}^t} (\text{er}_{A,B,D}(\kappa) > \epsilon) = \Pr_{\kappa \in \mathcal{D}^t} ((\text{er}_{A,B,D}(\kappa))^p > \epsilon^p) \\
\leq \left( \frac{n + p}{\epsilon \ell} \right)^p \\
\leq \delta
\]
for \( p = \lceil \ln(1/\delta) \rceil \) and \( \ell \geq \frac{\epsilon(n + \ln \frac{1}{\epsilon})}{\epsilon} \). The fact that learning \( \text{BOXES}_n \) reduces to learning \( \text{OBOXES}_{2n} \) completes the proof. \( \square \)

5 Pseudorandom sets for combinatorial rectangles

We refer the reader to the introduction for the motivation, notation, and history of this problem.

We will make use of an approximation result for \( \text{BOXES} \). Let \( \text{BOXES}_{k,n,m} \subseteq \text{BOXES}_{n,m} \) be the set of axis-parallel rectangles in \( \{0,1,\ldots,m-1\}^n \) that are nontrivial in at most \( k \) dimensions, analogously to \( \mathcal{R}_{m,k}^n \). Once again, \( \text{BOXES}_{n,m} \subseteq \text{BOXES}_{n,m} \). Furthermore, \( \epsilon \)-approximations for \( \text{BOXES}_{k,n,m} \) are defined analogously to \( \epsilon \)-approximations of \( \mathcal{R}_{m,k}^n \). An explicit family \( \{S_{m,k,n} \subseteq [0,m-1]^n : k, m, n \in \mathbb{N}, k \leq n\} \), where \( S_{m,k,n} \) is an indexable \( \epsilon \)-approximation for \( \text{BOXES}_{k,n,m} \), was presented in the full version of [11] with
\[
\log |S_{m,k,n}| = O(\log \log n + \log k + \log(1/\epsilon) + \log(1/\epsilon) \log([k/\log(1/\epsilon)])).
\]
(12)
This builds on some ideas from [14], and improves on all three constructions of [14]. (Though it may look surprising that the bound of (12) is independent of \( m \), it is shown in [14] that in the case of axis-parallel rectangles, we can effectively reduce the problem to the case where \( m \leq [4k/\epsilon] \) and where \( \epsilon \) is replaced by \( \epsilon/2 \); hence the independence from \( m \).)

In the following we first show how \( \epsilon \)-approximations for \( \mathcal{R}_m^m \) easily lead to \( \epsilon \)-approximations for \( \mathcal{R}_m^{n'} \) when \( n' \geq 2k^2/\epsilon \) (Section 5.1). Then we show our main \( \epsilon \)-approximation construction for \( \mathcal{R}_m^{n,k} \) (Section 5.2).

5.1 Reducing \( n \)

As mentioned a couple of sentences ago, the main point of Section 5.1 is to show how we can effectively "reduce" \( n \) to \( O(k^2/\epsilon) \), which then leads to Corollary 13.

Theorem 11 Let \( k \leq n \) be any positive integers, \( \epsilon \in (0,1) \), and \( n' = [2k^2/\epsilon] \). Suppose \( S' \) is an explicit indexable \((\epsilon/2)\)-approximation for \( \mathcal{R}_m^{n'} \). Then we can explicitly construct an indexable \( \epsilon \)-approximation \( S'' \) for \( \mathcal{R}_m^{n,k} \), with \( \log |S''| = \log |S'| + O(\log \log n + \log k + \log(1/\epsilon)) \).

We start with a simple hashing lemma.

Lemma 12 Suppose \( k \) and \( n \geq k \) are positive integers. Let \( \delta \in (0,1) \), \( \ell = [k^2/\delta] \), and \( \rho = \delta/(k^2\ell) \). Suppose \( \hat{Y} = (Y_1,Y_2,\ldots,Y_n) \) is sampled uniformly at random from \( S_{k,n,\rho} \). Then for any \( \{a_1,a_2,\ldots,a_s\} \subseteq [n] \) with \( s \leq k \), \( \Pr(Y_{a_1},Y_{a_2},\ldots,Y_{a_s} \text{ are all pairwise distinct}) \geq 1 - \delta \).
Proof: By the definition of $S_{t,2,n,p}$ we have, for any $1 \leq i < j \leq s$ and for any $p \in \{0,1,\ldots,\ell-1\}$, that $\Pr(Y_{ai} = Y_{aj} = p) \leq 1/\ell^2 + \rho$. Thus, $\Pr(Y_{ai} = Y_{aj}) \leq 1/\ell + \ell \rho = 1/\ell + \delta/k^2$. Hence,

$$\Pr(Y_{a1}, Y_{a2}, \ldots Y_{as} \text{ not all distinct}) \leq \sum_{i<j} \Pr(Y_{ai} = Y_{aj}) < (k^2/2)(1/\ell + \delta/k^2),$$

which is at most $\delta$ by our choice of $\ell$.

Proof of Theorem 11: We first describe $S''$ by saying how to generate a uniformly random sample $\tilde{X} = (X_1, X_2, \ldots, X_n)$ from it. Let $\delta = \epsilon/2$ and $\rho = \delta/(k^2n')$. Sample $Y = (Y_1, Y_2, \ldots, Y_n)$ uniformly at random from $S_{n',2,n,p}$, and define $f(i) = Y_i + 1$, for each $i \in [n]$; note that $f(i) \in [n']$. Independent of this random choice, sample $\tilde{Z} = (Z_1, Z_2, \ldots, Z_{n'})$ uniformly at random from $S'$, and define the final desired sample $\tilde{X}$ to be $(Z_f(1), Z_f(2), \ldots, Z_f(m))$. $S''$ is indexible, since $S_{n',2,n,p}$ and $S'$ are. Clearly, log $|S''| = \log |S'| + O(\log \log n + \log k + \log(1/\epsilon))$.

We now show that for any $R = S_1 \times S_2 \times \cdots \times S_n \in R_{m,k}$, $|\Pr(\tilde{X} \in R) - \vol(R)| \leq \epsilon$ holds, where the volume $\vol(R)$ is defined to be $(\prod_i |S_i|)/m^n$. Suppose $R$ is nontrivial in dimensions $a_1, a_2, \ldots, a_s$, where $s \leq k$. Now, by Lemma 12, $f(a_1), f(a_2), \ldots, f(a_s)$ are all distinct with a probability of at least $1 - \epsilon/2$; conditional on this, the definition of $S'$ implies that $|\Pr(\tilde{X} \in R) - \vol(R)| \leq \epsilon/2$. Also, if $f(a_1), f(a_2), \ldots, f(a_s)$ are not all distinct (which happens with a probability of at most $\epsilon/2$), $|\Pr(\tilde{X} \in R) - \vol(R)|$ can be at most 1, with probability 1. Hence,

$$|\Pr(\tilde{X} \in R) - \vol(R)| \leq (1 - \epsilon/2)\epsilon/2 + \epsilon/2 \leq \epsilon,$$

as required.

Recall that an indexible $\epsilon$-approximation $S'$ for $R_{m,k}$, with log $|S'| = O(\log m + \log n' + \log^2(1/\epsilon))$, is presented in [6]. Using this with Theorem 11 gives the following.

Corollary 13 There is an explicit indexible $\epsilon$-approximation $S''$ for $R_{m,k}$, with log $|S''| = O(\log \log n + \log k + \log m + \log^2(1/\epsilon))$.

5.2 The main construction

Theorem 17, the main theorem here, constructs an indexible $\epsilon$-approximation $S$ for $R_{m,k}$, with log $|S| = O(\log \log n + (\log m) \log(1/\epsilon) + (1/\epsilon) \log(\log(1/\epsilon)))$. We start with Lemma 14, which shows how to reduce the approximation of combinatorial rectangles to the corresponding question for axis-parallel rectangles, with appropriate parameters. We stress that this lemma is in itself quite simple, but will be useful later on when we show how to reduce our basic problem to the case of “small” $t$: $t = O(\log(1/\epsilon))$.

Lemma 14 For any positive integer $t \leq n$, there is an explicitly constructible and indexible $\epsilon$-approximation $T_{m,t,n,\epsilon}$ for $R_{m,t}$, with log $|T_{m,t,n,\epsilon}| = O(\log \log n + t \log m + \log(1/\epsilon))$.

Proof: Let $\epsilon' = \epsilon/m^t$. We shall show that taking $T_{m,t,n,\epsilon} = S_{m,t,n,\epsilon'}$ will suffice; the proof is then completed by invoking (12). Let $\tilde{X}$ be sampled uniformly at random from $S_{m,t,n,\epsilon'}$, and let $R = S_1 \times \cdots \times S_n$ be an arbitrary member of $R_{m,t}$. We now show that $|\Pr(\tilde{X} \in R) - (\prod_i |S_i|)/m^n| \leq \epsilon$, which will complete the proof. Assume w.l.o.g. that $R$ is trivial in dimensions $t+1, t+2, \ldots, n$; hence, $S_{t+1} = S_{t+2} = \cdots = S_n = \{0,1,\ldots,m-1\}$.

For any $\vec{p} = (p_1, p_2, \ldots, p_t)$ where $p_1 \in S_1, p_2 \in$
S_2, \ldots, p_t \in S_t$, let $R'(\vec{p})$ denote $\{p_1\} \times \cdots \times \{p_1\} \times S_{t+1} \times \cdots \times S_n$. $R'(\vec{p})$ is trivially a member of BOXES_{t,n,m}. Thus, 
\[ |\Pr(\vec{X} \in R'(\vec{p})) - 1/m^t| \leq \epsilon'. \] (13)

Now, 
\[ |\Pr(\vec{X} \in R) - (\prod_{i \in [n]} |S_i|)/m^n| = \left| \sum_{p_1 \in S_1, \ldots, p_t \in S_t} (\Pr(\vec{X} \in R'(\vec{p})) - 1/m^t) \right| \leq \sum_{p_1 \in S_1, \ldots, p_t \in S_t} |\Pr(\vec{X} \in R'(\vec{p})) - 1/m^t| \leq (\prod_{i \in [t]} |S_i|)\epsilon' \text{ (by (13))} \leq m^t\epsilon' = \epsilon, \]
as required.

Our approach now is to reduce the problem of constructing an $\epsilon$-approximation for $R^{'\text{n}}_{m,k}$ to that of constructing an $\epsilon'$-approximation for $R^{'\text{n}}_{m,t}$, where $t$ is "small" ($O(\log(1/\epsilon))$) and with $\epsilon'$ chosen appropriately. We may then invoke Lemma 14. Next, a useful lemma from the full version of [11]:

**Lemma 15** Let $Y_1, \ldots, Y_t$ be arbitrary binary r.v.s, and let $Z_1, \ldots, Z_t$ be independent binary r.v.s. Then, for any positive integer $s \leq t$, $|\Pr(\bigwedge_{i \in [t]} (Y_i = 0)) - \Pr(\bigwedge_{i \in [t]} (Z_i = 0))|$ is at most $2^{-s} + e^{1-s/(2s)} + \sum_{\ell=1}^{s} \sum_{A \subseteq [t]:|A| = \ell} |\Pr(\bigwedge_{i \in A} (Y_i = 1)) - \Pr(\bigwedge_{i \in A} (Z_i = 1))|$. 

We also need a well-known proposition (see, e.g., [9] and [11] for proofs):

**Proposition 16** For any positive integers $r, t$, $r \leq t$, we have $\sum_{i=0}^{r} \binom{t}{i} \leq (te/t)^{r}$. 

Define 
\[ k' = \min\{p \in \mathbb{N} : 2^{-p} + e \cdot e^{-p/(2s)} \leq \epsilon/2\}, \text{ and } \epsilon' = (\epsilon/2) \cdot (k'/(ke))^{k'}. \] (14)

Note that $k' = \Theta(\log(1/\epsilon))$, and that $1/\epsilon' \leq \text{poly}(1/\epsilon, ([k]/\log(1/\epsilon))]^{\log(1/\epsilon)})$. We now present our main result on approximating combinatorial rectangles:

**Theorem 17** There is an explicit and indestructible $\epsilon$-approximation $S$ for $R^{'\text{n}}_{m,k}$, with $\log |S|$ being 
\[ O(\log \log n + (\log m) \log(1/e) + (\log(1/e)) \log([k]/\log(1/e))). \]

**Proof:** Let $k'$ and $\epsilon'$ be as in (14). We now show that taking $S = T_{m,k',n,e'}$ (as introduced in the statement of Lemma 14) will suffice; the upper bound on $\log |T_{m,k',n,e'}|$ from the statement of Lemma 14 will then complete the proof.

To show this, let $R = S_1 \times \cdots \times S_n$ be an arbitrary member of $R^{'\text{n}}_{m,k}$. We now prove that for $\vec{X}$ sampled uniformly at random from $T_{m,k',n,e'}$, $|\Pr(\vec{X} \in R) - (\prod_{i \in [n]} |S_i|)/m^n| \leq \epsilon$, as required. We assume w.l.o.g. that $R$ is trivial in dimensions $k+1, k+2, \ldots, n$. For each $i \in [k]$, let: (i) $Y_i \in \{0, 1\}$ be a random variable that is 1 if $X_i \notin S_i$, and (ii) $Z_i \in \{0, 1\}$ be a random variable that is 1 if a point drawn uniformly at random from $[0, m-1]^n$ does not lie in $S_i$. Thus, our goal is to show that 
\[ |\Pr(\bigwedge_{i \in [k]} (Y_i = 0)) - \Pr(\bigwedge_{i \in [k]} (Z_i = 0))| \leq \epsilon. \] (15)
The proof technique now borrows largely from [11]. For each \( i \in [k] \), let \( T_i = \{0, 1, \ldots, m - 1\} - S_i \). Note that the condition \( s \leq t' \) in the statement of Lemma 15 is not crucial: if \( s > t \), we can always reset \( s := t \) for Lemma 15 to hold. Similarly, in our current context, if \( k' > k \), we can set \( k := k' \). By Lemma 15 and from the fact that \( 2^{-k'} + e \cdot e^{-k'/(2e)} \leq \epsilon/2 \) by definition of \( k' \), we see that

\[
\begin{align*}
| \Pr( \bigwedge_{i \in [k]} (Z_i = 0) ) - \Pr( \bigwedge_{i \in [k]} (X_i = 0) ) | & \leq \epsilon/2 + \sum_{\ell=1}^{k} \sum_{A \subseteq [k] : |A| = \ell} | \Pr( \bigwedge_{i \in A} (Y_i = 1) ) - \Pr( \bigwedge_{i \in A} (Z_i = 1) ) | \\
& \leq \epsilon/2 + \sum_{\ell=1}^{k} \sum_{A \subseteq [k] : |A| = \ell} | \Pr( \bigwedge_{i \in A} (X_i \in T_i) ) - (\prod_{i \in A} |T_i|)/m^\ell |.
\end{align*}
\]

We now bound \( | \Pr( \bigwedge_{i \in A} (X_i \in T_i) ) - (\prod_{i \in A} |T_i|)/m^\ell | \), for any generic set \( A \subseteq [k] \) with \( |A| = \ell \leq k' \). Since (i) \( T_{k', n, \epsilon} \) is an \( \epsilon' \)-approximation for \( \mathcal{R}_{m, k} \) by Lemma 14, and (ii) \( A \subseteq [k] \) with \( |A| \leq k' \), we see that \( | \Pr( \bigwedge_{i \in A} (X_i \in T_i) ) - (\prod_{i \in A} |T_i|)/m^\ell | \leq \epsilon' \). Thus, by the bound (16), \( | \Pr( \bigwedge_{i \in [k]} (Z_i = 0) ) - \Pr( \bigwedge_{i \in [k]} (X_i = 0) ) | \) is at most \( \epsilon/2 + \epsilon' \sum_{\ell=1}^{k'} (k) \), which is at most \( \epsilon/2 + (k \epsilon') \) by Proposition 16; this in turn is at most \( \epsilon \) by definition of \( \epsilon' \). Thus, as (15) has been established, and the proof is complete.

Note that the above proof will work with any \( \epsilon' \)-approximation \( S \) for \( \mathcal{R}_{m, k'} \), in place of the specific choice \( S = T_{m, k', n, \epsilon} \). Thus we get the following bootstrapping result:

**Theorem 18** Let \( k' \) and \( \epsilon' \) be as in (14). Then, any indestructible \( \epsilon' \)-approximation for \( \mathcal{R}_{m, k} \) is also an indestructible \( \epsilon \)-approximation for \( \mathcal{R}_{m, k} \). In particular, suppose, for all \( (n, m, k, \epsilon) \), there is an indestructible \( \epsilon \)-approximation \( S' \) for \( \mathcal{R}_{m, k} \) with \( \log |S'| = O(\log n + k + \log m + \log(1/\epsilon)) \). Then, for all \( (n, m, k, \epsilon) \), there is an indestructible \( \epsilon' \)-approximation \( S'' \) for \( \mathcal{R}_{m, k} \) with \( \log |S''| = O(\log n + k + \log m + \log(1/\epsilon) + \log(1/\epsilon) \log(\lfloor k/\log(1/\epsilon) \rfloor)) \).

Consider the particular case alluded to in the statement of Theorem 18. We note that explicit construction of an \( \epsilon \)-approximation \( S' \) for \( \mathcal{R}_{m, k} \) with \( \log |S'| = O(\log n + k + \log m + \log(1/\epsilon)) \), is an open problem as of now. However, we see even this specific result as promising, since: (i) \( \log |S'| \) is allowed to be quite high as a function of \( k \) (we just ask for linear dependence on \( k \), while logarithmic dependence on \( k \) can be shown existentially), and, indeed, such a construction has been achieved for axis-aligned rectangles [14, 11], and (ii) \( \log |S''| \) would be optimal for the common situation of \( k = O(\log(1/\epsilon)) \). Even if \( k \) is, say, \( O(\text{polylog}(1/\epsilon)) \), we would have \( \log |S''| = O(\log \log n + \log m + \log(1/\epsilon) \log(1/\epsilon)) \), a significant improvement over the \( O(\log \log n + \log m + \log^2(1/\epsilon)) \) that we derive above from [6].

6 Constructing certain Ramsey-type graphs

Recall the notion of an \( (s, t, n) \)-graph from the introduction; as mentioned there, we shall assume throughout w.l.o.g. that \( s \leq t \) (if we wish to construct an \( (s, t, n) \)-graph where \( s > t \), we can always take the complement of a \( (t, s, n) \)-graph). The basic probabilistic approach to showing that an \( (s, t, n) \)-graph exists, is to construct a random graph \( G \) on \( n \) vertices, in which each edge is put in
with a certain probability $p = p(s, t, n)$, independent of the other edges. The probability that any
given subset $A$ of the vertices with $|A| = s + 1$ induces a clique is $p(\binom{s + 1}{2})$; the probability that any
given subset $B$ of the vertices with $|B| = t + 1$ induces an independent set is $(1 - p)(\binom{t + 1}{2})$. Thus, if
$s, t, n$ and $p$ satisfy
\[
\left( \frac{n}{s + 1} \right) p(\binom{s + 1}{2}) + \left( \frac{n}{t + 1} \right) (1 - p)(\binom{t + 1}{2}) < 1,
\]
we get an $(s, t, n)$-graph with positive probability, i.e., we have shown that an $(s, t, n)$-graph exists. There are more involved probabilistic approaches than this to show the existence of $(s, t, n)$-graphs, e.g., using the “deletion method” [5] or, even stronger, the Lovász Local Lemma [35] or certain large-deviation inequalities [23]. If the basic probabilistic method (the usage of (17)) shows that an
$(s, t, n)$-graph exists, these more refined methods usually help show that an $(s, t^\alpha, n)$-graph exists, where $\alpha < 1$ is some constant. Since there are still enormous gaps between the nonconstructive and known constructive bounds for Ramsey-type graphs, we just follow the basic approach of using (17) for our simple constructive method. See [30] for an approach to constructing Ramsey graphs via derandomization techniques, which has a different motivation than our present one.

It can be checked that the method of conditional probabilities can be used to “constructivize” the
simple approach above, leading to a deterministic sequential algorithm of time complexity $\text{poly}(\binom{n}{s})$.
(Interestingly, this is also the best-known bound to check if a given graph is an $(s, t, n)$-graph.)

The two drawbacks here are that (i) the running time is rather high, and (ii) this approach seems inherently sequential, i.e., not parallelizable. We tackle the first problem by a “graph product” result of [1], and the second via $\epsilon$-approximations for axis-parallel rectangles.

**Graph products.** Given undirected graphs $G_1 = (V_1, E_1)$ and $G_2 = (V_2, E_2)$, the following product graph $G_1 \times G_2 = (V_1 \times V_2, H)$ is considered in [1]: $\{(u_1, v_1), (u_2, v_2)\} \in H$ iff either (i) $u_1 \neq u_2$ and $(u_1, v_2) \in E_1$, or (ii) $u_1 = u_2$ and $(v_1, v_2) \in E_2$. The following fact is shown in [1]: if $G_1$ is an $(s_1, t_1, n_1)$-graph and $G_2$ is an $(s_2, t_2, n_2)$-graph, then $G_1 \times G_2$ is an $(s_1 s_2, t_1 t_2, n_1 n_2)$-graph.

Applying this some $r$ times on a given $(s, t, \ell)$-graph $G$ thus shows that $G^r$ is an $(s^r, t^r, \ell^r)$-graph. Thus, if for some “small” $\ell$, we can efficiently construct an $(s, t, \ell)$-graph $G$, we can then efficiently construct a much larger graph $G^r$ that has $\ell^r$ vertices, with $s$ and $t$ getting replaced by $s^r$ and $t^r$ respectively.

**Approximations of distributions.** Let $X_1, X_2, \ldots, X_n$ be independent random variables taking on values in some finite set, say $\{0, 1, \ldots, m - 1\}$. We call a sample space (multi-set) $D$ (whose elements are members of $\{0, 1, \ldots, m - 1\}^n$) a $(k, \epsilon)$-approximation for $(X_1, X_2, \ldots, X_n)$ iff $\bar{Y} = (Y_1, Y_2, \ldots, Y_n)$ chosen uniformly at random from $D$ satisfies:

$$\forall I \subseteq [n] \text{ with } |I| \leq k, \forall a_1, \ldots, a_{|I|} \in \{0, 1, \ldots, m - 1\}, \ |Pr(\wedge_{i \in I}(Y_i = a_i)) - \prod_{i \in I} Pr(X_i = a_i)| \leq \epsilon.$$ 

Suppose $S_1$ is an explicit indexible ($\epsilon/2$)-approximation for BOXES$S_{k,n,t}$, where $\ell = \lceil 4k/\epsilon \rceil$. Then, it is shown in [14] that there exists a $(k, \epsilon)$-approximation $S_2$ for $(X_1, X_2, \ldots, X_n)$, such that: (a) $|S_2| = |S_1|$, and (b) given a uniformly random sample from $S_1$, a uniformly random sample from $S_2$ can be generated deterministically in time polynomial in $n$ and $m$, and in $\text{NC}$. In fact, the sample space $S_{m,k,n,\epsilon}$ (see (12)) of [11] can be constructed in $\text{polylog}(n + |S_{m,k,n,\epsilon}|)$ time using $\text{poly}(n, |S_{m,k,n,\epsilon}|)$ processors in an EREW PRAM. Thus we have, in particular,
Lemma 19 Let $X_1, X_2, \ldots, X_a$ be i.i.d. binary random variables. Then, for any $k \leq a$, there is a $(k, \epsilon)$-approximation $S_0$ for $(X_1, \ldots, X_n)$, such that: $|S_0| \leq \text{poly}(\log a, 1/\epsilon, ([k/\log (1/\epsilon)])^{\log(1/\epsilon)})$. Also, $S_0$ can be constructed by $\text{poly}(a, |S_0|)$ processors in $\text{polylog}(a+|S_0|)$ time on an EREW PRAM.

Theorem 20 There are absolute constants $c_0, c_1 > 0$ such that the following holds. Let $\ell \geq s \geq 3$ be any positive integers, $r$ be any positive integer, and $t = [c_0 \ell^{1/s}] \log \ell \geq s$. Then, an $(s^r, t^r, \ell^r)$-graph $G$ can be constructed by $\text{poly}(\ell^r, (\ell^r)^{\log((\ell^r)^{1/2})})$ processors on an EREW PRAM, in $\text{polylog}((\ell^r) + r)$ time.

Proof: We just show how to construct an $(s, t, \ell)$-graph $H$; we can then take the above-seen graph product $r$ times to “boost” the construction to get the desired graph $G$.

If we construct a random graph on $\ell$ vertices $1, 2, \ldots, \ell$ with each edge probability being $p = \ell^{-c_2/s}$ for an appropriate constant $c_2 > 0$, it can be verified that $s, t, p$ and $\ell$ satisfy

$$
\left( \frac{\ell}{s+1} \right) p^{(s+1)/2} + \left( \frac{\ell}{t+1} \right) (1-p)^{(t+1)/2} < 1/2.
$$

(The constant $1/2$ in the r.h.s. is arbitrary; it can be replaced by $1 - \ell^{-\Theta(1)}$, to get slightly better values for $s$ and $t$. We do not attempt this optimization here.) We can imagine the above random graph being constructed by generating $(\ell^r)$ i.i.d. binary random variables $\{X_i,j : 1 \leq i < j \leq \ell\}$, where $\Pr(X_i,j = 1) = p$ and where $i$ and $j$ are connected by an edge iff $X_i,j = 1$.

Construct, in parallel, a $(\ell^r, \epsilon)$-approximation $S_0$ for $\{X_i,j : 1 \leq i < j \leq \ell\}$, as guaranteed by Lemma 19; the value of $\epsilon$ will be determined below. Take a random sample (i.e., graph) from $S_0$. Since $S_0$ is a $(\ell^r, \epsilon)$-approximation, it is easily checked that the expected value of the sum of the number of induced cliques with $s+1$ vertices and the number of induced independent sets with $t+1$ vertices, is at most

$$
\left( \frac{\ell}{s+1} \right) (p^{(s+1)/2} + \epsilon) + \left( \frac{\ell}{t+1} \right) ((1-p)^{(t+1)/2} + \epsilon).
$$

For large enough $\ell$, $t \leq \ell/2 - 1$; hence, since $s \leq t$, $(s+1) \leq (t+1)$. Thus, if we take $\epsilon = (4 (\ell^r))^{-1}$, (18) shows that the above expected value is strictly smaller than 1. That is, at least one of the samples (graphs) in $S_0$ must be an $(s, t, \ell)$-graph, and hence can be found by parallel exhaustive search in $S_0$. (Note that we can easily check if a given $\ell$-vertex graph is an $(s, t, \ell)$-graph, using $\text{poly}(\ell)$ processors and $\text{polylog}(\ell)$ time, on an EREW PRAM.)

Using the cardinality of and construction time for $S_0$ specified by Lemma 19, we complete the proof of the theorem.

The two extremes for Ramsey-type $n$-vertex graphs are (i) where $s \sim t$, and (ii) where $s \ll t$, i.e., $s = c$ (some constant), and $t = n^{2c}$. While Theorem 20 can be used to construct a range of Ramsey-type graphs, the following corollary just lists these two extremes:

Corollary 21 For any $n$, the following Ramsey-type graphs can be constructed in parallel on an EREW PRAM. (i) $(2^{O(\sqrt{\log n})}, 2^{O(\sqrt{\log n})}, n)$-graphs using $n^{O((\log \log n)^{1/2})}$ processors and $\text{polylog}(n)$ time, and (ii) for any desired constants $\epsilon, \delta > 0$, $\epsilon < 1$, $(c, n^\epsilon, n)$-graphs using $\exp(n^\delta)$ processors and $O(n^\delta)$ time, where $c = c(\epsilon, \delta)$ is a constant.
Proof: We apply Theorem 20 using the following values for the parameters. For (i), we take both $s$ and $t$ to be $\Theta(\sqrt{\log n\log\log n})$, $\ell = 2\sqrt{\log n\log\log n}$, and $r = \Theta(\sqrt{\log n/ \log \log n})$. For (ii), we take $s = c'(\epsilon, \delta)$, i.e., a suitably large constant, $t = n^\epsilon$, $\ell = n^\delta$ and $r = \delta$, where $\epsilon$ and $\delta$ are sufficiently small positive constants, and $\delta$ is a sufficiently large constant.

Acknowledgments. Theorem 7 was proved with David Haussler and Nick Littlestone; we thank them for their contribution. We also thank the STOC 1997 program committee member(s) and referee(s), and the journal referees, for their helpful and detailed comments. We thank Oded Goldreich, who gave helpful suggestions about the paper. Finally, we thank Carlos Domingo for pointing out an error in the hardness proof of Section 3.3 in an earlier version of the paper.

A Proof of Lemma 4

If $X$ is a set, and $G$ is a set of $\{0, 1\}$ valued functions defined on $X$, define

$$
\text{VCdim}(G) = \max\{d : \exists x_1, ..., x_d \in X, \{(g(x_1), ..., g(x_d)) : g \in G\} = \{0, 1\}^d\}.
$$

We will make use of the following lemma. “Permissibility” is a technical measurability constraint (see Pollard’s [34] Appendix C).

**Lemma 22 ([37])** There is a constant $c$ such that, for all $X$, for all permissible sets $G$ of $\{0, 1\}$ valued functions defined on $X$, for all probability distributions $D$ on $X$ and $m \in \mathbb{N}$, and for all $0 < \epsilon, \delta < 1/2$, if $\text{VCdim}(G) = 1$, and $m \geq \frac{c}{\epsilon} \log \frac{1}{\delta}$, then

$$
D^m \left\{ \vec{x} : \exists g \in G \left| \left( \frac{1}{m} \sum_{i=1}^{m} g(x_i) \right) - \mathbb{E}_{u \in D}(g(u)) \right| > \epsilon \right\} \leq \delta.
$$

Next, we record the VC-dimension of the set of random variables whose probabilities are the $\alpha_k(b)$’s as $b$ varies. The proof is the same as the known proof for $\{(-\infty, b) : b \in \mathbb{R}\}$.

**Lemma 23** Choose $n, k \in \mathbb{N}$, $k \leq n$. For each $b$, define $g_b : \mathbb{R}^n \rightarrow \{0, 1\}$, by $g_b(\vec{u}) = 1 \iff u_k > b$. Then $\text{VCdim}(\{g_b : b \in \mathbb{R}\}) \leq 1$.

**Proof:** Choose $\vec{u}, \vec{v} \in \mathbb{R}^n$. Assume without loss of generality that $u_k \leq v_k$. Then there is not a $b$ such that $g_b(\vec{u}) = 1$ and $g_b(\vec{v}) = 0$.

Now we analyze the VC-dimension relating to the $\varphi_k(b)$’s.

**Lemma 24** Choose $n, k, r \in \mathbb{N}$, $k \leq n$, $\vec{a} \in \mathbb{R}^n$. For each $b$, define $g_b : (\mathbb{R}^n)^r \rightarrow \{0, 1\}$, by

$$
g_b(\vec{u}_1, ..., \vec{u}_r) = \begin{cases} 1 & \text{if } u_{1,k} > b \text{ and } \psi_{b_k}(\vec{a}_1, ..., \vec{a}_n) = 0 \\ 0 & \text{otherwise.} \end{cases}
$$

Then $\text{VCdim}(\{g_b : b \in \mathbb{R}\}) \leq 1$.  

23
**Proof:** Assume for contradiction that $\text{VCdim} \{ \{g_b : b \in \mathbb{R}\} \} > 1$. Then there exist $\vec{u}_1, ..., \vec{u}_r$ and $\vec{v}_1, ..., \vec{v}_r$ such that

$$\{(g_b(\vec{u}_1, ..., \vec{u}_r), g_b(\vec{v}_1, ..., \vec{v}_r)) : b \in \mathbb{R}\} = \{0, 1\}^2.$$ 

Since there exists $b$ such that $(g_b(\vec{u}_1, ..., \vec{u}_r), g_b(\vec{v}_1, ..., \vec{v}_r)) = (1, 1)$, we have $\psi_{\vec{u}_k}(\vec{u}_1, ..., \vec{u}_r) = \psi_{\vec{v}_k}(\vec{v}_1, ..., \vec{v}_r) = 0$. Thus, for any $b \in \mathbb{R}$

$$g_b(\vec{u}_1, ..., \vec{u}_r) = 1 \Leftrightarrow u_{1,k} > b$$
$$g_b(\vec{v}_1, ..., \vec{v}_r) = 1 \Leftrightarrow v_{1,k} > b$$

(19)

The fact that there is a $b$ such that $(g_b(\vec{u}_1, ..., \vec{u}_r), g_b(\vec{v}_1, ..., \vec{v}_r)) = (1, 0)$ implies in conjunction with (19) that $u_{1,k} > v_{1,k}$, but the fact that there is a $b$ such that $(g_b(\vec{u}_1, ..., \vec{u}_r), g_b(\vec{v}_1, ..., \vec{v}_r)) = (0, 1)$ implies in conjunction with (19) that $u_{1,k} < v_{1,k}$, a contradiction.

**Proof of Lemma 4:** Applying the usual Hoeffding bound (see [34, Appendix B]) proves (9). Combining Lemma 22 (the permissibility of the relevant sets of r.v.’s is easily verified), Lemma 23 and Lemma 24, proves (10).
Caption for Figure 1: If \( b \) and the target rectangle \( B \) are as indicated, \( \alpha_1(b) \) is the probability of the horizontally striped region, \( \beta_1(b) \) is the probability of the vertically striped region, and \( \varphi_1(b) \) is the probability of drawing the first instance from the portion of the horizontally striped region that does not overlap with the vertically striped region, and drawing the remaining instances from outside \( B \).
