Announcements

- Reading Chapter 16
  - problems: 16.3, 16.5, 16.7
- Project #4 is due in section on Wed.
- Project #5 will be handed out on Wed in section
Routing

- How does a packet find its destination?
  - problem is called routing

- Several options:
  - source routing
    • end points know how to get everywhere
    • each packet is given a list of hops before it is sent
  - hop-by-hop
    • each host knows for each destination how to get one more hop in the right direction

- Can route packets:
  - per session
    • each packet in a connection takes same path
  - per packet
    • packets may take different routes
    • possible to have out of order delivery
Routing IP Datagrams

- **Direct Delivery:**
  - a machine on a physical network can send a physical frame directly to a machine on another network
  - transmission of an IP datagram between two machines on a single physical network does not involve routers.
    - Sender encapsulates datagram into a physical frame, binds destination IP address to a physical hardware address and sends frame directly to destination
  - Sender knows that a machine is on a directly connected network
    - compare network portion of destination ID with own ID - if these match, the datagram can be sent directly
  - Direct deliver can be viewed as the final step in any datagram transmission
Routing Datagrams (cont.)

● **Indirect Delivery**
  - sender must identify a router to which a datagram can be sent
  - sending processor can reach a router on the sending processor’s physical network (otherwise the network is isolated!)
  - when frame reaches router, router extracts encapsulated datagram and IP software selects the next router
    • datagram is placed in a frame and sent off to the next router
Table Driven Routing

- Routing tables on each machine store information about possible destinations and how to reach them.
- Routing tables only need to contain network prefixes, not full IP addresses:
  - No need to include information about specific hosts.
- Each entry in a routing table points to a router that can be reached across a single network.
- Hosts and routers decide:
  - Can packet be directly sent?
  - Which router should be responsible for a packet (if there is more than one on physical net).
IP Routing Algorithm
(from Comer)

● RouteDatagram(Datagram, Routing Table)

● Extract destination IP address, D from datagram and compute network prefix N
  if N matches any directly connected network address
  else if the table contains a host-specific route for D
  else if the table contains a route for network N
  else if the table contains a default route
  else declare a routing error
How are routing tables obtained?

- **Routing with partial information**
  - Hosts do not need complete knowledge of all possible destination addresses
  - Host sends non-local information to (a) router

- **Routers can also route with partial information**
  - Consider a topology consisting of two completely connected subgraphs A and B
  - Subgraphs A and B share a single link
  - If a router in A sees an address it does not recognize, it sends the packet to B and vice-versa
Early Internet Architecture

- Small central set of routers that kept complete information about all destinations
- Larger set of outlying routers with only local information
- Default route for outlying routers is to a central router
- Local administrators can make changes
  - Local changes need to be propagated locally as well as to the central routers
Internet Core Router System

Arpanet Backbone

router 1

router 2

router 3

Local Net 1

Local Net 2

Local Net 3

Local Net 4
Internet Core Routing System

- Core routers exchange routing information so each will have complete information about optimal routes to all destinations

- This did not scale:
  - maintaining consistency among core routers became increasingly difficult
  - further difficulties arise when there are several backbones (e.g. ARPAnet and NSFnet)
  - if the core architecture is partitioned so that all routers use default routes, may induce routing loops
    - if routing information is not consistent, it is possible for a packet to be repeatedly routed in a circle until the packet times out
Distributed Systems

● Provide:
  – access to remote resources
  – security
  – location independence
  – load balancing

● Basic Services:
  – remote login (telnet and rlogin protocols)
    • extends basic access provided by normal login
  – file transfer (ftp, rcp)
    • can support anonymous transfers
  – information services (http)
    • two way protocols (request/response)
Distributed Systems

- A unified view of local and remote access
- Typical Services
  - data migration
    - provide only the data required, not the whole file
    - manage multiple copies as versions of the same object
  - process migration
    - a process can move from one machine to another
    - reasons for migration:
      - load balancing
      - data affinity
      - hardware/software preference (better configuration)
Distributed OS Design Issues

- **Should provide same model as a central system**
  - easy to understand for users

- **Needs to be scaleable**
  - will it work with 100, 1,000, or 10,000 nodes?

- **Failure Modes**
  - avoid a single central failure point
  - can loss performance or functionality with failure
    - but loss should be proportional to size of failure

- **Security**
  - should provide same guarantees on data integrity as a local system
