CMSC216: Practice Final Exam B SOLUTION

Spring 2025

University of Maryland

Exam period: 20 minutes Points available: 40

Problem 1 (10 pts): Examine the code to the right and describe what you expect its output to be. Explain why or why not you would expect to see any specific ordering in the output of the program.

SOLUTION: The processes will fork out in a "line" or "list" rather than branching in a tree. This is because each parent process falls into the if() consequence and will break out of the loop so will have only a single child. The order of output will start with the last child in the last iteration and proceed backwards to the original parent due to the placement of wait(). Example:

> a.out
iter 4, 13374 from 13373
iter 3, 13373 from 13372
iter 2, 13372 from 13371
iter 1, 13371 from 13370
iter 0, 13370 from 26018

```
1 #include <stdio.h>
2 #include <unistd.h>
3 #include <stdlib.h>
4 #include <wait.h>
5
6 int main(){
    for(int i=0; i<5; i++){</pre>
7
8
      pid_t p = fork();
      if(p != 0){
9
         wait(NULL);
10
        printf("iter %d, %d from %d\n",
11
                i,getpid(),getppid());
12
        fflush(stdout); // output now
13
                          // quit loop
14
        break;
      }
15
    }
16
    exit(0);
17
18 }
```

Problem 2 (10 pts): Nearby is the output of pmap showing page table virtual memory mapping information for a running program called memory_parts. Answer the following questions about this output.

(A) Certain addresses of memory are marked with the annotation r-x. Explain what this means and what kind of information you would expect to find in those addresses.

SOLUTION: The annotation means "read and execute" with no write permission. Typically this is a page of memory that would contain program text: executable instructions that should not be changed but can be fed to the processor to run the program. Examples are in the memory_parts program itself for its main() and in the shared library libc which has instructions for printf() and the like.

(B) Why does pmap only show a limited number of virtual addresses? What would happen if the program attempted to access an address not listed in the output? Example: address 0x00 is not in the listing.

SOLUTION: The page table only contains mapped pages for program. These mapped addresses are what is shown. The large number of other addresses are unmapped. Attempting to access these unmapped addresses will result in errors such as segmentation faults; this usually causes the program to be immediately terminated.

> pmap 7986

Problem 3 (10 pts): Nearby is a matrix/vector function which performs poorly. Create a new version of this function that **optimizes the memory access pattern**. Show your code and give a brief description of why the changes you made should improve performance.

```
1 int subcol_BASE(matrix_t mat, vector_t vec) {
    for(int j=0; j<mat.cols; j++){</pre>
\mathbf{2}
3
       for(int i=0; i<mat.rows; i++){</pre>
4
         int elij = MGET(mat,i,j);
         int veci = VGET(vec,i);
5
         elij -= veci;
6
         MSET(mat,i,j,elij);
7
       }
8
    }
9
    return 0;
10
11 }
```

```
1 ////// SOLUTION ///////
2 int subcol_opt(matrix_t mat
3
                  vector_t vec)
4 {
     if(mat.rows != vec.len){
6
      printf("mat.rows (%ld) != vec.len (%ld)\n",
7
              mat.rows,vec.len);
      return 1;
 8
    }
9
10 // Loop over rows
    for(int i=0; i<mat.rows; i++){</pre>
11
       // subtract same vec el each time
12
13
       int veci = VGET(vec,i);
       // across row
14
       for(int j=0; j<mat.cols; j++){</pre>
15
         int elij = MGET(mat,i,j);
16
         elij -= veci;
17
         MSET(mat,i,j,elij);
18
      } // end INNER LOOP across row
19
    } // end OUTER LOOP over rows
20
    return 0;
21
22 }
```

WHY CHANGES IMPROVE PERFORMANCE:

SOLUTION: The new version favors cache by visiting matrix elements across rows rather than down columns. This eliminates the memory stride and will improve speed.

Problem 4 (5 pts): To further optimize the subcol_opt() function, a common strategy is to utilize multiple threads. Describe briefly how this might be done. Include in your answer.

(A) How the work to be done is divided among threads

(B) How changes to shared data will be coordinated to ensure safety.

SOLUTION: Set up a "worker" function where each thread would select some rows to work on. Working across rows as in the optimized version will continue to run fast. (A) Each thread subtracts elements from vec away from corresponding elements in its assigned rows of the matrix: 2 threads operation on a matrix with 100 rows would have thread 0 subtract off of rows 0-49 and thread 1 from 50-99. A main thread could pass logical thread ID numbers, thread counts, and pointers to the matrix/vector via a "context" struct. (B) Even though the Matrix is shared, threads will NOT need to coordinate with a mutex in this case as they are each changing different elements in the matrix: thread 0 and thread 1 will never alter the same elements.

Problem 5 (5 pts): Consider the code sample nearby which prints logging messages to either the screen or a log file as dictated by the USE_LOGFILE variable. Describe how one could eliminate the conditional if/else and all the fprintf() calls using I/O redirection system calls within the program.

SOLUTION: If USE_LOGFILE is true, do the falling. Call dup() system call to duplicate STDOUT_FILENNO then dup2(logfd,STDOUT_FILENO) so that anything that is printed to the screen instead goes into the log file. One would need to open() the log file to get a File Descriptor for it and possible restore Standard Output later, but this line of attack would mean only unconditional printf() calls are needed.

```
1 {
     if(USE_LOGFILE){
 2
       fprintf(logfile,"Updating DB\n");
 3
     7
 4
 \mathbf{5}
     else{
       printf("Updating DB\n");
 6
 \overline{7}
     7
 8
     update_db();
9
     if(USE LOGFILE){
10
       fprintf(logfile,"Syncing files\n");
     }
11
12
     else{
       printf("Syncing files\n");
13
     3
14
     file_sync();
15
16
     ...;
17 }
```
